

INTERNATIONAL DOCTORAL THESIS

Prevalence and associated factors of the use of opioids in the treatment of chronic non-cancer pain. Perspective of the general Spanish population and the experience of patients.

Helena De Sola Perea

Cádiz (Spain) 2020

INTERNATIONAL DOCTORAL THESIS

**Prevalence and associated factors of the use of
opioids in the treatment of chronic non-cancer
pain. Perspective of the general Spanish population
and the experience of patients.**

Helena De Sola Perea

Dissertation presented to obtain the doctorate degree in the Health Science program
from the University of Cádiz.

ACKOWNOLEDGEMENT

En primer lugar, quiero agradecer a mi directora de tesis Inmaculada Failde, por abrirme camino y guiarme en el mundo de la investigación. Gracias por darme la oportunidad y apostar por mí, con esa entrega y disposición que te caracteriza. Estos años han sido de trabajo y esfuerzo, pero sobre todo de aprendizaje y entusiasmo. Gracias por contagiarme el amor por la investigación. Asimismo, gracias por haberme dado la libertad y facilitarme los medios para la ejecución de esta tesis.

Un trabajo de investigación es siempre fruto de ideas, proyectos y esfuerzos previos. Por ello, agradecer a la Universidad de Cádiz y a la Fundación Grüenthal, y en particular a Juan Antonio Micó, por fomentar y promover la investigación. A la Sociedad Española del Dolor y a la Fundación Española del Dolor que, tras acogerme como miembro, financiaron mi estancia predoctoral en el extranjero y posibilitaron con ello la mención internacional de mi tesis.

A mi querida amiga y compañera Bego Ojeda, la que me trajo de la mano al “Observatorio del Dolor”. Gracias por tu insistencia. Nunca un consejo de alguien ha tenido una repercusión tan importante y enriquecedora en mi vida. Gracias.

Alejandro Salazar, mi mentor y co-director. La vida es mucho más fácil con personas como tú. Desde el principio me has tenido entre tus quehaceres. Gracias por tu paciencia, dedicación y búsqueda de la perfección. Gracias por tus ganas de enseñarme y conseguir que herede algunas de tus muchas virtudes. Gracias porque sin duda, sin ti nada sería lo mismo.

A los compis del Observatorio, por hacer que el trabajo en equipo sea tan fácil y fructífero. María Dueñas, has marcado el camino para los que hemos venido detrás. Gracias por habernos aconsejado siempre desde la tranquilidad y la experiencia. Eres el ejemplo a seguir. A las “LeTris”, Patricia Ortega y Leticia del Reguero, por ser un revulsivo de espontaneidad, generosidad y ganas. Es genial tener compis y colegas como vosotras. A Jose A. Moral, por abrirnos un campo de investigación diferente. Jenifer Palomo, gracias por la paciencia de aguantarme en este último tirón.

Al grupo de Salud Pública de Cádiz, por su compromiso y dedicación con la Salud Pública. En especial a Juan Antonio Córdoba, por haberme hecho la mejor recomendación que me podían hacer sobre el lugar de la estancia. A Antonio Escolar, por tu atención y tu cariño, por recordarme

para qué sirve lo que hacemos, y no perder el punto de mira. A Pepe Almenara, gracias por tus indicaciones cada vez que he necesitado ayuda en la parte burocrática, guiándome en todo el proceso del doctorado desde entrevista hasta el final.

To Miguel San Sebastian and Anna-Karin Hurtig for accepting and facilitating my pre-doctoral stay in The Epidemiology Department at Umeå University, Sweden. A Isabel Goicolea, ha sido un placer haber coincidido contigo en esta experiencia. Me has enseñado y mostrado un nuevo camino en la forma de hacer investigación, además, de ser un apoyo muy importante. A Amaia Maquibar, por tu disponibilidad y tu crucial trabajo en el desarrollo del que espero sea el primero de muchos trabajos juntas. To Anne, Ida, Parvin, Jennifer, Iratxe, Edwina, Yue, Chama... for welcoming me and making me feel at home. All of you turned my stay in Umeå into one of the most enriching experiences of my life. Not only professionally, but also personally.

A los participantes de los estudios de esta tesis por compartir generosamente sus experiencias. También a los médicos y enfermeras de la Unidad de Dolor en el Hospital Universitario "Puerta del Mar", por permitirnos ser parte de su equipo durante un período de tiempo, especialmente el Dr. José Manuel Trinidad.

A mis amigas, una pieza fundamental en mi vida. Es un orgullo rodearme de personas como vosotras, con las que es tan fácil ser tú misma. Gracias por los momentos de escucha y apoyo.

A la familia Perea, por estar siempre todos a una y, en especial a mis abuelos, por la dedicación y el amor que me han dado.

A mi familia política, por enseñarme que en la vida es todo cuestión de actitud y positividad.

A mis padres, mis cimientos, por vuestro esfuerzo constante en darme lo mejor, darme libertad de elección y confiar en mis decisiones. Sois un orgullo de padres. A mi hermano Elio, las ramas de un árbol pueden crecer en diferentes direcciones, pero nuestra raíz es una. Os quiero.

A Lola, por compartir y formar parte del mejor de mis proyectos. Gracias.

STRUCTURE OF THE THESIS

This thesis is presented as a compendium of publications. In the case of this thesis, four articles have been included.

In addition, it is intended to obtain the International Mention, which adds requirements such as writing some sections in both English and Spanish. Therefore, the structure of the thesis is as follows:

Firstly, we present the list of articles on which this thesis is based, showing the progress and the evolution in our work. Then, we continue with the list of scientific communications presented in national and international congresses, the glossary and the list of opioids mentioned throughout the thesis.

The abstract is presented in both English and Spanish.

The introduction presents an overview of all the topics covered in this thesis, without particularizing in each article. After this, there is a section presenting a justification of the thesis and its storyline. This section has been included for clarity in the presentation of the results and to explain the whole process carried out.

The objectives are presented as a global aim that agglutinates and summarizes the objectives of each article, serving as a general aim of the whole thesis. Subsequently, the specific objectives of each study are detailed. For coherence in the exposition, the hypotheses are also separated into the specific hypotheses of each study.

The methods and the results sections are also detailed for each of the four articles. Next, there is a general discussion of the combined results of the four articles. The final section presents the conclusions of the thesis as a whole. The bibliography covers all the references that have been cited in the common part of the thesis, while the specific bibliography of each article can be found in its corresponding section.

LIST OF SCIENTIFIC ARTICLES

This thesis is composed of the following articles:

1. Prevalence of therapeutic use of opioids in chronic non-cancer pain patients and associated factors: a systematic review and meta-analysis.

2. The evolution of opioid-related mortality and potential years of life lost in Spain from 2008 to 2017. Differences between Spain and the United States.

This paper was published in the journal *Current Medical Research and Opinion* with a Journal Impact Factor of 2.345, included in the second quartile of the category Medicine, General & Internal category of the Journal Citation Report SCI section

3. Opioids in the Treatment of Pain. Beliefs, Knowledge, and Attitudes of the General Spanish Population. Identification of Subgroups Through Cluster Analysis.

This article was published in the *Journal of Pain and Symptoms Management* with a Journal Impact Factor of 3.378, included in the first quartile of the Health Care Sciences / Services category of the Journal Citation Report SCI section.

4. Living with opioids: A qualitative study with patients with chronic low back pain. This article was accepted to be published in the *Health Expectations* with a Journal Impact Factor of 2.847, included in the first quartile of the Health Care Sciences / Services category of the Journal Citation Report SCI section

LIST OF SCIENTIFIC COMMUNICATIONS

The communications to congresses resulting from this work are:

1. De Sola H, Maquibar A, Failde I, Salazar A, Palomo J, Goicolea I. Experiences of chronic pain patients with long-term opioid treatment. Oral Communication. GLOSSARY

Abuse	persistent or sporadic excessive drug use unrelated to acceptable medical practice.
Adherence	the extent to which a person's behavior agrees with the recommendations from a health care provider.
Addiction	a primary, chronic, neurobiological disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.
Analgesic	a medicine that reduces pain.
Dependence	a state of adaptation that is manifested by a drug class specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.
Diversion	the movement of controlled drugs from licit to illicit distribution channels or to illicit use.
Long-term opioid therapy (LTOT)	The use of opioids on most days for more than 3 months.
Misuse	any use outside of prescription parameters, including misunderstanding of instructions, self-medication of sleep, mood, or anxiety symptoms, and compulsive use driven by an opioid use disorder.
Morphine	a potent opiate analgesic drug frequently used in medicine.
Opiate	the origin of the opium substance; that is, substances extracted from the capsule of the opium plant. The active opiates found in the opium poppy are morphine, codeine, thebaine and papaverine. By extension, the chemical products derived from morphine, such as oxycodone and hydrocodone, are also called opiates.
Opioid	commonly referred to as prescription opioids, medications that have been used to treat moderate to severe pain. Analgesic agents used to designate endogenous or exogenous substances that have a similar effect to morphine on the central nervous system; they can be natural or synthetic.
Overuse	to use more drugs than prescribed by the doctor.

Pain intensity term used interchangeably with pain severity and referring to the level of pain experienced and reported by the patient.

Pain severity see “Pain intensity”.

Prolonged-release or extended-release (formulation) are mechanisms used in tablets (pills) and capsules to dissolve a drug over time in order to be released more slowly and steadily into the bloodstream while having the advantage of being taken at less frequent intervals than immediate-release formulations of the same drug.

Tolerance a reduction in the sensitivity to a pharmacological agent following repeated administration. As a consequence, increased doses are required to produce the same magnitude of effect.

Withdrawal syndrome the occurrence of a complex syndrome of uncomfortable symptoms or physiological changes caused by an abrupt discontinuation or decrease in a dosage after repeated administration of a pharmacological agent. Withdrawal syndrome can also be caused by the administration of an antagonist.

OPIOIDS MENTIONED THROUGHOUT THE THESIS

	Drugs	Route of administration
Weak Opioids	Tramadol	- Oral forms: solid or liquids. - Parenteral administration (injection)
	Buprenorphine	- Sublingual tablets - Transdermal patch
Strong Opioids	Tapentadol	- Oral forms: Prolonged-release or immediate-release tablets
	Oxycodone	- Oral forms: Prolonged-release or immediate-release tablets - Parenteral administration
	Fentanyl	- Tablets to suck - Sublingual tablet - Oral tablet - Transdermal patch - Nasal spray.
	Morphine	- Prolonged-release tablets - Parenteral administration (injection)

ABSTRACT

Aims

The general aim of this thesis was to study the situation of opioid treatments for chronic non-cancer pain (CNCP). The specific aims were: first, to determine and synthesize the prevalence of the therapeutic use of opioids in patients with CNCP, and to analyze the factors associated with their use through a systematic review of the literature and a meta-analysis; second, to investigate the evolution of opioid-related mortality and potential years of life lost in the general population in Spain from 2008 to 2017 and to compare the results by gender and age with the United States; third, to describe the current perspective of the Spanish population toward opioid use in the treatment of pain and to identify groups of individuals based on their point of view on these drugs; and finally, to explore the experiences of patients with chronic non-malignant low back pain in Spain undergoing long-term treatment (>3 months) with opioids.

Methods

In the first study of the thesis, a systematic review of the current literature and meta-analysis were performed using two databases (PubMed and SCOPUS). For this purpose, original cross-sectional studies published in English or Spanish between 2009 and 2019 with the main objective of determining the prevalence of opioid use in CNCP patients were included. Search terms and search strategies were adapted to each database. The articles included in the meta-analysis were stratified according to the source of the sample, the type of pain, and the duration of the opioid treatment.

The second paper of the thesis is a descriptive study using retrospective annual data from 2008 to 2017 in the general population of Spain and the United States. Information on the population and opioid-related deaths stratified by age and sex was obtained from the Spanish National Statistics Institute and from the Centers for Disease Control and Prevention (CDC) WONDER Multiple Cause of Death Database, according to the ICD-10 codes. Years of life lost, crude and standardized mortality rates were calculated and compared with the results in US.

The third article included in the thesis is a cross-sectional study carried out on a nationwide representative sample of 1,299 Spanish adults. Data and information about beliefs, knowledge, fears, opinions and, attitudes towards the use of opioids were collected via a computer assisted telephone interview (CATI). A descriptive analysis of the variables studied and a cluster analysis were performed to identify groups of people based on these parameters. In addition, a

multinomial logistic regression model was developed to analyze the variables related to the clusters.

Finally, in the last part of the thesis, a qualitative study was performed using semi-structured interviews. Recruitment and data collection were conducted from April to October 2018. Fifteen participants were recruited from the Pain Clinic in Hospital Puerta del Mar. Inclusion criteria for the study were: adults suffering from chronic non-malignant low back pain and receiving long-term treatment (>3 months) with opioids. We conducted interviews until very similar experiences were described in the last interviews as in the previous ones. A constructionist perspective was adopted. The interviews were analyzed by the qualitative content method described by Graneheim and Lundman, and developed categories and themes discussed in the light biomedicalization theoretical framework.

Results

In the first article, we identified that of the 1062 potential articles found in the systematic review, 23 studies fulfilled the inclusion criteria. In the general population, the prevalence of long-term (>3 months) opioid use was 2.3% (95%CI:1.5%-3.6%), the prevalence of short-term opioid use was 7.3% (95%CI:4.3%-11.9%), and 5.8% among people with chronic low back pain (95% CI:0.5% - 45.5%). The prevalence of opioid use among patients from the health records or medical surveys was 41% (95%CI:23.3%-61.3%). Finally, in patients with musculoskeletal pain, the prevalence was 20.5% (95%CI:12.9%-30.9%) and 24.5% among patients with fibromyalgia (95%CI:22.9%-26.2%). A higher prevalence of opioid use was observed among the following groups: men; younger people; patients receiving prescriptions of different types of drugs; smokers and patients without insurance or with non-commercial insurance. In addition, non-white and Asian patients were less likely to receive opioids than non-Hispanic white patients.

The results of the second study showed that the crude rate of opioid-related deaths per 10⁵ inhabitants has changed from 1.68 in 2008 to 2.25 in 2017 in Spain, with around 30,000 years of life lost per year. The most affected groups were middle-aged men and women over 65, and the main cause of death was accidental poisoning. The standardized rates per 10⁵ inhabitants across the years were between 1.19 and 1.62 in Spain and between 11.17 and 20.68 in the US population.

In the analysis of the beliefs, fears, opinions and attitude towards opioids analyzed in the third article in the general Spanish population, three groups of subjects were identified: a group with a positive point of view (N=448) composed of people >65 years who would accept a treatment if prescribed and were less fearful of these drugs; a group with a moderate point of view (N=337) formed of younger subjects with university education, and who were better informed about opioids, afraid of these drugs (OR=2.67), and more frequently associated them with drowsiness (OR=2.58), nausea (OR=3.04), and tolerance (OR=2.16); a third group with a negative point of view (N=468), with a lower educational level who would more often reject treatment with opioids, and were more afraid of them (OR=3.95), considering that they may not be able to stop the treatment (OR=3.04) and that the opioids may produce tolerance (OR=3.03).

Finally, in the analysis of the experiences of people with chronic pain (CP) taking opioids, described in the fourth article, we developed one overarching theme - living with opioids: dependence and autonomy while seeking relief - which crosscut three categories: 1) The long pathway to opioids due to the invisibility of pain, 2) Opioids: from blind date to a long-term relationship and 3) What opioids cannot fix. The results show that the long and difficult process to obtain effective treatment was a fundamental part of the struggle to cope with pain, involving long-term relationships with the health system. The two first categories refer to the journey participants made to get a diagnosis and treatment with opioids, and their experiences during this long and difficult process, which was quite unique for each person. The third category describes the circumstances and situations experienced by the patients before and after the painful episode started, and how these influenced the whole process.

Conclusions

The results obtained in the different studies lead to the following conclusions:

- The prevalence of opioid use in patients with CNCP varies depending on the duration of treatment and the population analyzed, with higher prevalence in clinical studies based on health registries and occasional users. Age, race, and the access to the health service delivery system and its characteristics are the factors most related to the use of opioids.
- Regarding opioid-related mortality, an opioid overuse crisis does not seem a likely scenario in Spain. However, it is a social problem that requires special health surveillance, particularly in middle-aged men and women over 65.

- The different perspectives of patients regarding the use of opioids to treat pain should be taken into consideration by physicians when designing strategies to inform patients about the treatment of pain with opioids. This should promote their correct use, and prevent their misuse in particular.
- The experiences of patients should be considered to a greater extent by healthcare professionals when giving information about opioids and setting treatment goals. Greater consideration of the social determinants of health that affect chronic pain experiences might lead to more effective solutions to chronic pain.

RESUMEN

Objetivo

El objetivo general de esta tesis fue estudiar la situación de los tratamientos con opioides en pacientes con Dolor Crónico No Oncológico (DCNO). Para ello, en primer lugar, realizamos una revisión sistemática de la literatura y un meta-análisis para determinar y sintetizar la prevalencia del uso terapéutico de opioides en pacientes con DCNO, así como los factores asociados a su uso. En segundo lugar, nos planteamos investigar la evolución de la mortalidad relacionada con los opioides y los años potenciales de vida perdidos en la población general española entre 2008 y 2017, compararlos por género y edad y con los Estados Unidos. El tercer objetivo, fue describir la perspectiva de la población española sobre el uso de opioides en el tratamiento del dolor, e identificar grupos de individuos en función de su punto de vista con respecto a estos medicamentos. Finalmente, nos propusimos explorar las experiencias de pacientes con dolor lumbar crónico no oncológico bajo tratamiento de larga duración (>3 meses) con opioides.

Metodología

En el primer estudio de la tesis se realizó una revisión sistemática de la literatura y un meta-análisis utilizando dos bases de datos (PubMed y SCOPUS). Con este objetivo, se incluyeron artículos originales publicados en inglés o español entre 2009 y 2019 con un diseño transversal, cuyo objetivo principal era conocer la prevalencia del uso de opioides en pacientes con DCNC. Los términos y las estrategias de búsqueda se adaptaron a cada una de las bases de datos. Los artículos que se incluyeron en el meta-análisis se agruparon según la procedencia de los datos de la muestra, el tipo de dolor y la duración del tratamiento con opioides.

En la segunda parte de la tesis llevamos a cabo un estudio descriptivo utilizando datos anuales retrospectivos de mortalidad relacionada con los opioides de 2008 a 2017 en población general española y Estados Unidos. La información sobre la población y las muertes relacionadas con los opioides estratificadas por edad y sexo se obtuvieron del Instituto Nacional de Estadística de España y de la Base de datos de causas múltiples de muerte WONDER de los Centros para el Control y la Prevención de Enfermedades (CDC), de acuerdo con los códigos ICD-10. Se calcularon los años de vida perdidos y se aportan tanto en tasas de mortalidad brutas y estandarizadas y se comparan con los resultados en los Estados Unidos.

En la tercera parte de la tesis, realizamos un estudio de corte transversal a nivel nacional en una muestra representativa de 1.299 adultos españoles. Los datos fueron recolectados a través de entrevistas telefónicas asistida por ordenador (CATI) sobre las creencias, conocimientos,

miedos, opiniones y actitudes hacia el uso de opioides. Se realizó un análisis descriptivo de las variables estudiadas, un análisis clúster para identificar grupos de personas basados en estos parámetros y un modelo de regresión logística multinomial para analizar las variables relacionadas con cada grupo de individuos.

Finalmente, en la última parte de la tesis, realizamos un estudio cualitativo, usando entrevistas semi-estructuradas. El reclutamiento y la recolección de los datos se llevaron a cabo entre abril y octubre de 2018. Los datos fueron recogidos a través de 15 entrevistas a pacientes de la Unidad de Dolor en el Hospital Puerta del Mar. El criterio de inclusión para el estudio fue: adultos que sufrían dolor lumbar crónico no maligno y tomaban un tratamiento de larga duración con opioides. Se realizaron entrevistas hasta que en las últimas entrevistas se describían experiencias muy similares a las entrevistas previas. Se adoptó una perspectiva constructivista. Se realizó un análisis del contenido cualitativo tal y como describen Graneheim and Lundman, y se desarrollaron categorías y temas que fueron discutidos en el marco teórico de la biomedicalización.

Resultados

De los 1062 potenciales artículos encontrados en la revisión sistemática, 23 cumplieron los criterios de inclusión. A partir de la información analizada, se observó que, en población general, la prevalencia del uso de opioides de larga duración (>3 meses) fue 2.3% (IC 95%: 1.5% -3.6%) y la prevalencia del uso de opioides de tratamientos de corta duración fue 7.3% (IC 95%: 4.3% - 11.9%). En los datos de los pacientes provenientes de registros sanitarios o encuestas médicas, la prevalencia fue 41% (IC 95%: 23.3% -61.3%). Finalmente, en pacientes con dolor musculoesquelético, la prevalencia fue 20.5% (IC 95%: 12.9% -30.9%) y en pacientes con fibromialgia, 24.5% (95%CI: 22.9%-26.2%). Además, se observó un mayor uso en hombres, en jóvenes, en pacientes que tienen prescritos diferentes tipos de medicamentos, en fumadores y en pacientes sin seguro o con seguro médico no comercial. Además, los pacientes no blancos y los pacientes asiáticos tenían menos probabilidades de recibir opioides que los pacientes blancos no hispanos.

Entre los resultados obtenidos en el segundo manuscrito, la tasa bruta de mortalidad relacionadas con los opioides por cada 10⁵ habitantes ha cambiado de 1.68 en 2008 a 2.25 en 2017 en España, con alrededor de 30.000 años de vida perdidos por año. Los grupos más afectados fueron hombres de mediana edad y mujeres mayores de 65 años. La principal causa de muerte fue el envenenamiento accidental. Las tasas estandarizadas por 10⁵ habitantes a

lo largo de los años se situaron entre 1.19 y 1.62 en España y entre 11.17 y 20.68 en la población de los Estados Unidos.

Respecto a los resultados obtenidos en el tercer artículo, en el que se analizan las creencias, miedos, opiniones y actitudes hacia los opioides en la población española general, destaca que se identificaron tres grupos de sujetos de acuerdo a su perspectiva sobre los opioides. Un grupo con un punto de vista positivo (N = 448) compuesto por personas >65 años que aceptarían un tratamiento con opioides si se lo recetaran y que tenían menos miedo a tomar estos medicamentos; un grupo con un punto de vista moderado (N = 337) formado por sujetos más jóvenes con educación universitaria, mejor informados sobre los opioides, temerosos de estos fármacos (OR = 2.67), y que lo asociaban con más frecuencia con somnolencia (OR = 2.58), náuseas (OR = 3.04) y tolerancia (OR = 2.16); un tercer grupo con un punto de vista negativo (N = 468), que se caracterizaba por tener un nivel educativo más bajo, que rechazaría con mayor frecuencia un tratamiento con opioides en el caso de que se lo recetaran, más miedo de tomarlos (OR = 3.95), considerando que es posible no ser capaces de detener el tratamiento (OR = 3.04) y que producen tolerancia (OR = 3.03).

Finalmente, en el análisis de los resultados obtenidos en el cuarto artículo sobre las experiencias de personas con DC que toman opioides, se obtuvo un tema principal: “Vivir con opioides: dependencia y autonomía mientras se busca alivio al dolor”, que engloba tres categorías: 1) “El largo camino hacia los opioides debido a la invisibilidad del dolor”, 2) opioides: de una cita a ciegas a una relación duradera y 3) “Donde los opioides no llegan”. Los resultados muestran que la búsqueda de un tratamiento efectivo es fundamental en la lucha para mitigar el dolor, conllevando una larga relación con el sistema de salud. Las dos primeras categorías se refieren al largo y difícil proceso que hacen los participantes para obtener un diagnóstico y tratamiento con opioides, y sus experiencias durante esta búsqueda larga y difícil, que es única para cada persona. La tercera categoría describe las circunstancias y situaciones experimentadas por los pacientes antes y después del comienzo del episodio doloroso, y cómo han influido en todo el proceso.

Conclusiones

En vista de los resultados obtenidos en los diferentes estudios, se pueden extraer las siguientes conclusiones:

- La prevalencia del uso de opioides en pacientes con DCNO varía según la duración del tratamiento y la población analizada, con una mayor prevalencia en estudios clínicos basados en registros de salud y en pacientes con un tratamiento de corta duración. La edad, la raza, el

acceso y las características del sistema de sanitario son los factores más relacionados con el uso de opioides.

- Una crisis debida de uso excesivo de opioides no parece que sea un escenario probable en España. Sin embargo, es un problema social que requiere una vigilancia especial, particularmente en hombres de mediana edad y mujeres mayores de 65 años.
- El médico debe tener en cuenta las distintas perspectivas de los pacientes respecto al uso de opioides al diseñar estrategias para informarlos sobre el tratamiento del dolor con opioides. Esto debería servir para promover su uso correcto, especialmente evitando su mal uso.
- Las experiencias de los pacientes deben ser consideradas en mayor medida por los profesionales de la salud al aportar información sobre los opioides y establecer objetivos de tratamiento. Una mayor consideración de los determinantes sociales de la salud que afectan las experiencias de dolor crónico podría conducir a soluciones más efectivas en su tratamiento.

INTRODUCTION

1. CHRONIC PAIN

1.1 Definition and classification

Pain is a complex, multidimensional phenomenon that is defined by the International Association for the Study of Pain (IASP) as a “distressing experience associated with actual or potential tissue damage, with sensory, emotional, cognitive, and social components” ¹. In its acute form, pain is useful as it enables the protection of the physical well-being of an organism. By contrast, chronic pain (CP) exceeds the role of a warning signal and becomes a threat in itself ². As such, CP is no longer considered a symptom or a nerve impulse, but a disease itself, becoming the sole or predominant clinical problem in some patients ¹.

CP is, by its nature, a disease which is difficult to evaluate and assess with physical explorations or complementary techniques. Therefore, it has been defined in terms of duration. Hence, the clinical history of the patient has a relevant role in the diagnosis. Although there is a non-specific set of cut-off scores to consider pain as chronic, the most recognized definition is set by the IASP, defining CP as a pain that persists or recurs for longer than three months ³. However, this definition of CP does not include the specific characteristics of pain, such as frequency, taxonomy, intensity or severity, necessary for better patient care and to facilitate the comparison of research outcomes ⁴.

For the first time, the 11th Revision of the International Classification of Diseases (ICD-11) recognizes codes of CP in a systematic classification, representing an opportunity to improve the assessment of pain and treatment throughout all health care systems ⁵. It includes seven main codes; one code for “chronic primary pain,” where chronic pain is the disease, and six codes for chronic secondary pain syndromes, where pain is developed in the context of another disease. “Chronic primary pain” is defined as chronic pain in one or more anatomical regions and is characterized by significant emotional distress (anxiety, anger/frustration or depressed mood) and functional disability (interference in daily life activities and reduced participation in social roles). Chronic primary pain is multifactorial, since biological, psychological, and social factors contribute to the pain syndrome.

The 6 categories for chronic secondary pain considered in the ICD-11 are:

(1) Chronic cancer-related pain, i.e., all chronic pain that arises in the context of cancer or its treatment.

(2) Chronic postsurgical or post-traumatic pain, i.e., all chronic pain from surgery or accidental trauma.

(3) Chronic neuropathic pain.

(4) Chronic secondary headache or orofacial pain.

(5) Chronic secondary visceral pain, i.e., chronic pain arising from causes such as persistent visceral inflammation or vascular or mechanic causes.

6) Chronic secondary musculoskeletal pain, i.e., rheumatoid arthritis.

1.2 Epidemiology of chronic pain

Pain is a multivalent, dynamic, and ambiguous phenomenon that is notoriously difficult to quantify. Yet, even with such limitations, CP is undoubtedly a health problem that has reached worldwide epidemic proportions. Globally, 1 in 5 adults has been estimated to suffer from pain, and another 1 in 10 adults are diagnosed with chronic pain each year ⁶. In Europe, CP affects 19% of the population, with important differences among countries, ranging from 13% in the United Kingdom and Ireland to 30% in Norway ⁷. In Spain, the prevalence is 16.6%, and there is at least one adult with pain in 1 out of every 4 homes [10].

In the United States, it is estimated that 20.4% of adults has suffered CP ⁸. Among Asian adults, CP ranges from 7.1% (Malaysia) to 61% (Cambodia and Northern Iraq) ⁹. In Niger, Africa, the population suffering pain is younger than in Asia, the average age of the sufferers being 48.28 years and predominant in the male sex ¹⁰. Therefore, CP affects all populations and all groups around the world, regardless of age, sex, race or ethnicity, although it is not equally distributed in all societies. The wide variation in prevalence reflects, in turn, differences in the sociodemographic, economic or climatological characteristics of the populations. A high prevalence of CP may reflect, for example, the aging of the population, adverse weather conditions or precarious working conditions. Likewise, this variety may also depend on how CP is defined and the evaluation methods used in epidemiological studies ¹¹.

The duration of CP ranges from 2 to 15 years, the median in European countries being 7.0 years ⁷. Spain, Finland and Portugal have the longest duration (around 10 years), the majority of the sufferers reporting moderate or severe pain ^{7,12,13}. The most common location of pain is in the back. More than 40% had joint pain, most frequently knee-pain. One in five had head or neck pain, and the same proportion had hand or leg pain ¹⁴.

It has been shown that the combination of osteoarthritis and rheumatoid arthritis is the most common cause of pain (42%)¹⁵. The annual prevalence of chronic low back pain has been reported to range from 15% to 45%. Disorders of the musculoskeletal system, such as low back pain, neck pain, other musculoskeletal pain, and osteoarthritis of the knee are also major health problems in many countries^{16,17}. Trauma or surgery caused chronic pain in 15% of the cases. Rheumatoid arthritis and migraine headaches occurred in less than 10%¹⁵.

1.3 Social and demographic determinants of chronic pain

In addition to the well-defined biological factors, there are a variety of factors that can influence an individual's pain. CP has been defined as a changing experience that may depend on culture, history and individual conscience. Likewise, social and demographic factors, including sex/gender, age, marital status, family relations, or socioeconomic status are all important elements of the context for pain experience^{18,19}.

Regarding sex/gender, the prevalence of CP is known to be higher among women²⁰. However, despite a large volume of experimental research in this area, a consistent pattern of sex differences in pain sensitivity, expression and impact has not yet emerged. What is known from clinical studies is that women use more analgesic medication and are more sensitive to both the dosage and type of medication. Yet, experimental research has not successfully solved the key of the differences between sexes²¹. The increased incidence of CP conditions observed in females could result from greater susceptibility to such conditions or them being more likely than men to report pain²².

Thus, to analyse the differences between men and women, it is also interesting to analyse them from a gender perspective, implying considerations of cultural contingencies and how the status of the sexes in different societies influences embodiment, expressions, and social cognition. Women's descriptions of symptoms, their explanations and consequences are shown to be dependent on social interaction with family members, friends, neighbours, work-mates, and doctors²³.

Regarding age, CP is also highly prevalent among older adults. In aging populations, the prevalence of multiple chronic medical conditions is increasing worldwide, with a growing impact on healthcare systems [10]. In addition, these aging problems are expected to increase¹¹ because of the increase in life expectancy and aging trends in the workforce, among other reasons²⁴. CP is also a risk factor for accelerated cognitive deterioration, suggesting potential shared mechanisms between persistent pain (or its treatment) and dementia. Since older adults

are underrepresented in clinical trials testing treatments for chronic pain, the potential impacts of polypharmacy and frailty on reported outcomes and side effect profiles are largely unknown²⁵.

Socioeconomic factors have been identified as a predictor of the development of certain chronic diseases^{26,27}. Furthermore, the co-occurrence of two or more chronic medical conditions has been proven to be more prevalent in deprived patients^{28,29}. Deprivation is defined as a manifest material or social disadvantage relative to the local community or the broader society. A lower socioeconomic status is linked with poor access to products and services which, directly or indirectly, influence health, such as healthy food, housing conditions or medical care. The socioeconomic gradient in health can be further explained on the basis of psychosocial factors and stress associated with living in an environment of relative socioeconomic disadvantage. These psychosocial factors could be either direct (e.g. allostatic load) or indirect (e.g. unhealthy behaviours due to stress, such as excess drinking and smoking)³⁰. Thus, deprivation should be defined not only as a manifest material or social disadvantage but also as a predictor of certain chronic diseases, it therefore being important that health services take it into consideration.

Interesting relationships between CP and family structure have been observed. Many serious and chronic illnesses require family and friends to take on the role of informal caregiver. Informal caregiving refers to activities involved in providing assistance to relatives or friends who are unable to provide for themselves³¹. In this vein, previous studies³² have reported that individuals living alone or who are divorced have a higher prevalence of CP.

It is worth mentioning that, although these risk factors are sometimes difficult or impossible to modify, and therefore difficult to manage from a medical perspective, it is essential to recognize them, since they determine the susceptibility of a population to suffer from CP, and must be carefully evaluated.

1.4 Impact of chronic pain

- Comorbidities

CP is frequently associated with other pathologies. The presence of illnesses favours the appearance of pain and, in turn, pain determines the presence of other pathologies, but the nature of this relationships and the degree of contribution to the risk of suffering pain is not well established. However, patients with comorbidities are known to suffer more intensity of pain than those with CP alone³³. The illnesses coexisting with pain can be physical and mental.

Depression and anxiety are among the most common mental problems frequently encountered in daily clinical practice. Like other illnesses/pathological conditions, the associations between pain and depression and/or anxiety seem to be reciprocal, although the evidence that pain predisposes depression and/or anxiety is more consistent than vice versa ³⁴. It has been observed that 50% of CP patients report depression, in contrast to 2% to 9% of the general population ³³. Rates of anxiety among pain patients (50%) are also markedly higher compared to reported rates within the general population using similar assessment tools ³⁵. The associated symptoms of depression and anxiety such as inability to concentrate, disturbed sleep, pessimistic mood, fatigue and loss of motivation may weaken patients' motivation to participate in rehabilitation and adhere to treatments ^{36,37}.

- **Individual impact**

Apart from depression and anxiety, evidence suggests that sleep disturbances are also correlated with the intensity of pain ^{36,38,39}. Strong negative moods may increase or perpetuate the impact of sleep disturbances on patients' pain. In addition, it is not difficult to see how negative mood, sleep disturbances and pain might each act to accentuate one another if there is no intervening action to disrupt such a self-perpetuating cycle. Addressing negative mood is likely to have a beneficial effect on patients with pain or their perception of their ability to cope with pain ⁴⁰.

Another important problem to consider is the effect of pain on everyday activities and participation in social roles. The negative emotions and irritability that frequently affect these patients have an impact on their interpersonal relationships and social functioning. Pain intensity is also significantly associated with engagement in social activities, individuals reporting more intense pain being more likely to report difficulties engaging in these activities ⁴¹. Thus, the deterioration of physical functioning and pain-related mental health are the aspects that contribute most to hindering social integration capacities.

It has been argued that no other health problem causes as much disability as CP ¹⁴. The physical limitations experienced by patients produce greater reliance on care and assistance, which is mostly provided by the family. Hence, family members usually have to carry out new duties, such as monitoring pain, giving medication and dealing with side effects of the sufferer. The uncertainty about performing these new tasks adequately could lead to both physical and psychological deterioration in the family environment ⁴², which can also perpetuate the problems associated with pain, since patients are concerned about the impact of their illness on others, resulting in guilt, distress and feelings of having become a burden to others ⁴³.

Furthermore, it is notable that the individuals whose CP produces greater physical limitations are more likely to request sick leave ⁴⁴. Some authors ⁴⁵ have shown that there is a significant relationship between CP and the individual's capacity to work. Almost a third of the individuals suffering CP needed to take sick leave and over 10% lost their jobs as a result of their CP. This problem also increases employer costs through reduced productivity, high turnover rates, absenteeism and health care expenses.

Therefore, the evaluation of patients should be multifactorial, involving emotional aspects, attitudes to facing pain, cognition, coping strategies and, additionally, the impact of the pain on their daily lives.

- **Social impact**

As already been mentioned, the impact of CP extends beyond the individual and has deep and reciprocal consequences for social networks involving family, friends and work. Hence, for a better understanding of the burden of CP, it is important to study it as a whole ⁴⁶.

CP is a medical and a public health issue with an important socio-economic burden. In Europe, the total costs of CP represent 3–10% of the gross domestic product (GDP) ⁴⁷, including direct and indirect costs. Direct costs are associated with analgesic drugs and nonpharmacological treatments, medical visits, hospitalizations, and complementary tests ⁴⁸. Indirect costs are associated with sick leave and presenteeism, and the intangible costs related to quality of life ⁴⁹.

Hospitalization is the largest single component of direct costs, while social benefits (e.g. disability allowance and unemployment benefits) comprise the biggest single component of indirect costs. In Sweden in 2008, for example, the indirect costs of sick leave longer than 15 days and early retirement accounted for 59% of the total costs in patients with diagnoses related to CP, followed by outpatient and inpatient care ⁴⁷

Indeed, it is estimated that the annual economic cost of CP in Spain is over €3000 million (2.5% of the GDP). Likewise, people with CP are absent from the workplace 40% more than individuals who do not suffer from pain, in addition to being a 30% less productive ⁵⁰.

1.5 Chronic pain and its pharmacological management

As mentioned above, pain is a complex phenomenon that is influenced by biological, psychological and social factors. Therefore, a multidisciplinary approach is recommended in the treatment of pain ⁵¹. Taking into account the manifestations of the disease, the characteristics of pain, psychological coping skills and factors related to lifestyle, the treatment can include pharmacological and non-pharmacological interventions.

Some studies ^{12,52} have shown that around 70% of CP patients receive pharmacological treatment for their pain and that the initial pain assessment of a CP patient involves obtaining information about the location, duration, and characteristics of the pain, as well as the impact of persisting pain on various aspects of the person's life such as sleep, emotional state, relationships, development and physical function. The health-care provider should try to investigate the associations of the pain with any triggers by asking about any known aggravating and relieving factors. The health professional should also ask which pain management treatments have previously been used and their efficacy.

To establish pharmacological treatments, many doctors are governed by the therapeutic scale of the World Health Organization (WHO), basing their decisions mainly on the intensity of pain.

The therapeutic scale states three steps for the use of analgesics, starting with simple non-opioid analgesics (acetaminophen and prostaglandin synthesis inhibitors-NSAIDs-). The second step involves weak opioids, and in a third step, if the pain increases or is persistent, strong opioids are prescribed. Each step involves more analgesic power than the previous one and treatment always starts with non-opioid analgesics, constituting the basis of pain management in combination with adjuvant therapy with medications (e.g. anticonvulsants, antidepressants, etc.).

Adjuvant drugs, such as anticonvulsants and/or antidepressants may also be prescribed. In addition, once the third step of analgesia has been applied without adequate pain control, patients should be referred to Pain Clinic, where different therapeutic options will be proposed based on the predominant type of pain.

2. OPIOIDS

2. 1 A brief history of opioids

The term opioids originally referred to the alkaloid compounds found in opium (*derived from the Greek word «opos»: juice*), obtained from the sap of the *Papaver somniferum* poppy (Figure 1), and has been used for thousands of years for recreational and medicinal purposes.

Figure 1. *Papaver somniferum*

Records exist that the Sumerians first grew poppies in around 3400 BC. The use of opium spread through all the important civilizations of Eurasia, where it was used for medical purposes, including the treatment of pain ⁵³. At the beginning of the 19th Century, the German pharmacist Friedrich Wilhelm Sertürner became the first person to extract the active ingredient from poppy seeds and named the new compound morphine in honor of Morpheus, the Greek god of dreams. During the 19th Century, the consumption of opium, especially for recreational purposes, extended through the west, dependence on it increasing too. During the American Civil War (1861-1865), soldiers were given a hypodermic syringe and a supply of morphine, which they could inject as a painkiller if they suffered war injuries. When the war was over, American society was faced with a new epidemic, none other than addiction to the opioids that had been provided to the soldiers with a complete lack of control ⁵⁴.

Due to the large number of morphine addicts, it was necessary to find a new substance with similar painkilling properties but without the addiction problems. In 1874, heroin, the first semi-synthetic opioid was created and given the brand name HeroinTM, from the word “hero”, who in Greek mythology was a person with special strength and ability. It was marketed by the company Bayer for the treatment of respiratory illnesses, and was advertised as being more effective and less addictive than morphine ⁵⁵. Sales of heroin quickly soared as its use extended around the whole world. However, the fact that it was highly addictive was not observed until 1913, when the manufacturer halted its production. Years later, with the help of technological advances, opioids and their derivatives were found to result in powerful addiction.

Consequently, the beginning of the 20th Century saw the first regulations for substances and their control. Progressive restrictions were imposed on the sales of heroin and other opioids. The 1914 Narcotics Tax Act in the United States made it illegal for doctors to prescribe opioids to treat addiction, and in 1925, the League of Nations completely prohibited the sale of heroin,

which resulted in increases in the underground trafficking of the raw materials for producing this opioid.

During the second half of the 20th century, most physicians prescribed opioids for acute and cancer pain. Opioids have improved the quality of life of millions of patients with oncological pain. In contrast, they were rarely prescribed to patients with CP. Some authors indicated ⁵⁶ that a lack of knowledge about the use of opiates by health professionals (physicians) and users (patients) led to a negative image of opioids in general. Opioids were often associated with advanced disease, imminent death, illicit drug addiction, euthanasia, potential risks of abuse, excessive sedation, and fear ⁵⁷. This set of beliefs and inappropriate attitudes concerning the deleterious effects of opioid administration for pain relief were defined as opiophobia ⁵⁸. This has been related to the reduced prescription of these drugs by health professionals and lower consumption by patients ⁵⁹.

2.2 Recent history of opioids

In the late 1990s, healthcare systems in the United States recognized pain as a “5th vital sign”. Some years later, in 2001, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) established the mandatory early recognition and management of pain as a standard of care ⁶⁰. It is also noteworthy that Purdue Pharma, a pharmaceutical company which had developed OxyContin, an extended-release formulation of oxycodone, was involved in funding and providing educational videos and materials regarding the need for better pain management ⁶¹.

In the recent history of opioids, it is important to mention the fundamental role of OxyContin. OxyContin is a semisynthetic opioid that was first marketed as a less addictive alternative to “narcotic” drugs, such as morphine and heroin, being aggressively marketed in USA for the opioid-based management of moderate-to-severe cancer and non-cancer pain. More than half of the total number of OxyContin prescriptions were written by primary care physicians rather than pain specialists, and prescribed for all types of pain syndromes. As a result, the sales of opioid analgesics quadrupled in the US during 1999-2010. More specifically, from 2002-2009, the number of prescriptions for extended-release opioids rose from 9.3-22.9 million, an increase of 146% ⁶².

It is no coincidence that, in the same period, the number of opioid overdoses in America quadrupled according to the CDC. This massive increase in prescribing has occurred despite no overall change in the amount of pain Americans having been reported in that time period ⁶³. As

access to prescription opioids tightens, consumers increasingly are turning to dangerous street opioids, heroin, or fentanyl, either in isolation combined with cocaine or other drugs.

Apart from the wide use of oxycodone, the United States had the highest consumption of morphine worldwide, twice that of the European Union as a whole. Morphine use is well controlled in Europe and has declined in recent decades in many European countries, with the main exceptions of Austria and Switzerland ⁶⁴, even though the WHO indicated that morphine, the oldest known opioid, is the gold standard for the treatment of moderate to severe pain ⁶⁵.

Although the consumption of opioids between 2000 and 2008 increased in Europe, the use of oral morphine has decreased. Some authors concluded that this is because the behavior of physicians is still largely contrary to guidelines, suggesting that cultural rather than legal factors are mainly responsible for morphinophobia ⁵⁷. Reasons for the limited consumption of morphine in other countries may include stigma, the shift from oral to other formulations, its possible side effects, as well as its low costs, that leave small profit margins for the manufacturers ⁶⁴.

The most frequently used opioid in Europe is fentanyl. Its increased use has largely contributed to the rise in total opioid consumption, particularly since the early 2000s. Its easy administration and patient compliance, along with strong marketing of its transdermal use, may explain such an increase. Spain is the only country in Southern Europe in which fentanyl consumption is at the level of Western and Northern European countries. This could be due to the regulation adopted in 1995 and several informative campaigns promoted since the early 2000s to facilitate the use of opioids ⁶¹. In contrast to the United States, oxycodone consumption has increased modestly in Europe, and is still much lower than that of fentanyl.

Many factors have contributed to the unprecedented increase in opioid use and abuse in recent years in the United States. One is the inadequate training received by physicians in pain management; another is the heightened awareness of undertreated pain among the general public and the media, leading to an increasing demand for opioids from patients, in particular those with mental health or substance abuse disorders⁶⁶.

2.3 The global burden of opioids

As mention above, opioid prescription has become more common in the general population in the last two decades ⁶⁷. This trend has occurred in several countries. However, in some of them, such as the USA and Canada, it has been accompanied by an increase in reported opioid abuse and deaths ⁶⁸. Several authors ⁶⁹ have underlined the consequences of opioid over-prescription in the USA, estimating that 1 in 65 deaths was opioid related in 2016, representing an enormous burden in years of life lost (YLL). Indeed, the YLL from opioid-related deaths exceed those

attributable to hypertension, HIV/AIDS, and pneumonia. Loss of life due to opioid overdose poses a considerable societal burden, especially among adults aged 25 to 34 years, where this burden is highest. In this age group, 1 in 5 deaths is opioid related in the USA. Moreover, the recreational use of opioids among adolescents is increasing, with approximately one in seven high school seniors and university students reporting past non-medical use of these drugs ⁷⁰.

In addition, prescription opioid overdose, abuse, and dependence implies high costs. In the USA, it was estimated that the societal costs attributable to the abuse of opioid prescription rose from \$55.7 billion in 2007 ⁷¹ to \$78.5 billion in 2013 ⁶³. This cost is attributable to direct healthcare costs, costs related to losses of productivity, and costs to the criminal justice system. However, many of them are inestimable, including the social impact on opioid-dependent people, and the suffering of family members as witnesses to addiction or to fatal overdose ⁶³.

By early 2017, there were daily reports of the diversion and misuse of prescription opioids within a number of states and counties across the USA. In fact, the crisis in opioid overdose deaths exceeded all other drug-related deaths or traffic fatalities ⁶³. Thus, in October of 2017, President Donald Trump called for the ongoing opioid epidemic to be declared a nationwide public-health emergency ⁷².

3. CHRONIC PAIN AND OPIOIDS

Pain is the leading cause of disability and work absence throughout most of the industrialized world, especially when it becomes chronic ⁷³. Population growth and aging are strongly related to this fact. As life expectancy increases, people are living a greater number of years with impaired health and more disability ¹⁷. Additionally, the percentage of people with pain has grown worldwide due to the adoption of lifestyle behaviors that are known to increase cancer risk and pain as a consequence, such as smoking, poor diet, physical inactivity, and reproductive changes ⁷⁴.

Clinical evidence has long supported the use of opioids as a first-line treatment for moderate to severe pain, particularly for pain related to cancer ⁷⁵. This has been reflected in increased opioid consumption since the late 1980s, partly a result of the efforts made by the WHO and other organizations to assert the essential need of opioid analgesics for the treatment of chronic cancer and non-cancer pain in particular ⁶⁴.

However, despite the WHO recommendations, opioid use in the context of CNCP has sparked controversy since patients with CP have reported a high incidence of adverse effects of opioid therapy, including dependence, overdose, and withdrawal ⁷⁶.

The concerns of patients regarding possible adverse effects, the limited knowledge of physicians about pain management and the lack of a proper evaluation of pain at the diagnostic stage may explain why the use of opioids to treat CP remains limited in comparison with cancer pain ⁶⁴. In addition, some authors ⁷⁷ have highlighted that the media has focused on the negative effects of opioid use for pain, such as stigma and misuse, rather than the positive benefits of increased pain relief and improved quality of life.

In some countries, apart from social, cultural, and educational factors, there are regulatory and governmental restrictions which negatively affect prescribing by physicians and occasionally lead to undertreatment. Even though the regulation of controlled drugs is not intended to impede legitimate prescribing for appropriate medical purposes, the impact of controlled substance therapy, specifically with chronic non-malignant pain, continues to be a contentious issue for pain specialists ⁷⁸.

In addition, treatment with opioids also provokes controversy regarding the benefits it provides in CP patients since some studies ^{79,80} show that most people who use opioids continue to report moderate or severe pain and that functional improvements are often scarce. On the contrary, some professionals have reported that patients treated with opioids seem to experience significant functional benefits in addition to reductions in pain intensity, which reflects the variability of response to treatment depending on the patient ⁷⁶.

JUSTIFICATION

Considering the foregoing, it is justified to review the prevalence of opioid use in patients with chronic non-oncological pain in the scientific literature, as well as to explore the factors associated to their use, since the prevalence of their use varies widely according to the country and the circumstances of the patients.

In countries where the prescription of opioids has increased considerably in recent years, it has been observed that people frequently misuse these drugs, this becoming the first cause of death in some countries. Hence, due to the need for the safe and rational use these drugs, we consider it of interest to investigate the evolution of opioid-related mortality and potential years of life lost in the general population in Spain from 2008 to 2017 and to determine the differences between Spain and the USA.

It is also noteworthy that the prescription of opioids has increased or decreased throughout history depending on the beliefs of health professionals and patients about these drugs, leading to undertreatment of the pain in some cases and misuse/overuse of these drugs in others. Therefore, we considered it necessary to know the perspective of the general Spanish population towards opioids in the treatment of pain to know in which point we are located.

Furthermore, there are certain controversies regarding the benefits and the consequences provided by opioid treatment. Therefore, we considered that it is important to know the experience of the patients who are under treatment with this type of medication.

THE STORY LINE OF THE THESIS

The initial situation that provided the motivation for this thesis was the low opioid prescription rates observed in Spain compared with other countries. When the doctoral project started in 2016, we deliberated if CP could be somehow undertreated due to perceptions and negative beliefs associated with opioids. However, at the beginning of the following year, a report was released by the “Spanish Drug Agency” commenting on the rise of opioid use in Spain ⁸¹. For this reason, we decided that the first step would be to investigate the prevalence of the use of opioids through a systematic review of the literature.

Later that year (2017), a public health crisis and a state of alert associated with an increase in opioid-related morbidity and mortality were declared in the United States. We decided it was crucial to know if Spain was following the same tendency regarding the evolution of opioid-related mortality and potential years of life lost. That was, therefore, the aim of the second paper.

After the literature review, and taking into account the importance of the attitude, knowledge and beliefs of the population about opioids, the aim of the third paper was to know the perspective of the Spanish population related to the use of this analgesic.

Then, the next natural step was to know the experiences of CP patients under long-term treatment with opioids. To this end, in the fourth (and last) manuscript, we gave voice to the protagonists of this situation through the methodology of qualitative research.

OBJECTIVES

GLOBAL AIM

The main aim of this thesis was to study the situation of the opioid treatments for chronic non-oncological pain.

SPECIFIC OBJECTIVES

- **Study 1.** *Prevalence of therapeutic use of opioids in chronic non-cancer pain patients and associated factors: a systematic review and meta-analysis.*

To determine the prevalence of the therapeutic use of opioids in patients with CNCP and to analyze the factors associated with their use through a systematic review of the literature.

To provide a summary measure of the information obtained through a meta-analysis.

- **Study 2.** *The evolution of opioid-related mortality and potential years of life lost in Spain from 2008 to 2017. Differences between Spain and the United States.*

To investigate the evolution of opioid-related mortality and potential years of life lost in the general Spanish population from 2008 to 2017 and to compare them by gender and age.

To know the differences between Spain and the USA.

- **Study 3.** *Opioids in the Treatment of Pain. Beliefs, Knowledge, and Attitudes of the General Spanish Population. Identification of Subgroups Through Cluster Analysis.*

To describe the current beliefs, opinions, and attitudes of the Spanish population toward opioid use in the treatment of pain.

To identify groups of individuals based on their point of view regarding these drugs and to analyze the factors that influence this perspective in each of the identified groups.

- **Study 4.** *Living with opioids: A qualitative study with patients with chronic low back pain.*

To explore the experiences of patients with chronic low back pain in Spain undergoing long-term treatment with opioids.

HYPOTHESIS AND RESEARCH QUESTION

Based on the previous literature, specific hypotheses have been stated for each study.

- *Study 1. Prevalence of therapeutic use of opioids in chronic non-cancer pain patients and associated factors: a systematic review and meta-analysis.*

- 1.1 The prevalence of opioid use found in the studies of health records or medical surveys will be higher than the prevalence found in studies carried out in the general population.
- 1.2 The prevalence of short-term opioid treatments will be higher than long-term opioid treatments.
- 1.3 Patients with musculoskeletal pain will be more likely to receive opioid treatment than patients with other pathologies.
- 1.4 Patients with more types of drugs prescribed will be more likely to receive opioid treatment.

- *Study 2. The evolution of opioid-related mortality and potential years of life lost in Spain from 2008 to 2017. Differences between Spain and the United States.*

- 2.1 The crude rate of opioid-related mortality will be higher in 2017 than in 2008 in Spain.
- 2.2 The number of opioid-related years of life lost will have increased in this period.
- 2.3 The group most affected by opioid-related mortality will be middle-aged men.
- 2.4 The standardized rates in the US population will be higher compared to standardized rates in Spain.

- *Study 3. Opioids in the Treatment of Pain. Beliefs, knowledge, and attitudes of the General Spanish population. Identification of subgroups through cluster analysis.*

- 3.1 The general Spanish population will refer beliefs about opioids similar to those described in other countries when relating them to concepts such as pain, illegal drugs or cancer.
- 3.2 Morphine will be the best known and correctly identified as an opioid by the population.
- 3.3 The prevalence of the Spanish population taking an opioid treatment will be similar to other southern European countries, such as Portugal.
- 3.4 The opinions, fears and attitude of the Spanish general population towards opioids will be determined by sex, age and previous contact with the treatment.
- 3.5 People that reject opioid treatment will do so for fear of side effects.
- 3.6 Taking into account the perspective of the Spanish population, we can differentiate at least 3 groups of people according to their point of view towards opiates.

- *Study 4. Living with opioids: A qualitative study with patients with chronic low back pain.*

4.1 What are the experiences of people with non-oncological chronic low back pain under long-term treatment with opioids in Spain?

METHODS

Study 1. Prevalence of therapeutic use of opioids in chronic non-cancer pain patients and associated factors: a systematic review and meta-analysis.

Study design

A systematic review of the current literature and meta-analysis.

Search strategy

The search was performed in the PubMed and SCOPUS databases. Original cross-sectional studies published from 2009 to 2019 in English or Spanish were included. The terms/keywords of interest were “opioid”, “analgesics”, and “pain”. The terms were combined with the tag for searching in the title, abstract and keywords. The search terms and search strategies were adapted to each database. Once the search strategies for both databases were executed, we imported all the references found into the Covidence online tool⁸². The process of duplicate removal, screening, data extraction and risk of bias analysis were performed by this web-based systematic review tool.

Eligibility criteria

According to the predefined inclusion criteria, an article was selected when its main aim was to determine the prevalence of the use of opioids in CNCP humans (all ages), provided these data were shown within the paper or it was possible to calculate them from it. Articles related to CNCP located in specific body regions (e.g. musculoskeletal CP) were also included. Thus, the term “chronic non-cancer pain” was not included in the search strategy in order not to limit the searches to studies presenting only data from general CNCP.

Studies including patients with cancer pain, focusing on the opinions or attitudes of physicians about opioid prescription or on the disorders derived from their consumption were excluded.

Study selection

The study selection was performed by two authors who independently screened the title and abstract of all of the papers. Shortlisted studies were then analyzed in depth according to the inclusion criteria and their reference lists were also screened to identify studies that could be included in the review. The quality of the studies were assessed following the Critical Appraisal

Checklist for Analytical Cross-sectional studies from the Joanna Briggs Institute ⁸³. This checklist consists of 8 items.

Extraction of data

From the selected papers, information was extracted about the primary aim of the study, characteristics of the population studied, sample source, sample size, method for data retrieval, and response rate. Likewise, the definition of CP considered in each article, prevalence of CP in the population studied, prevalence of opioid use, the method for obtaining this prevalence data, and the factors associated with opioid use were collected.

Statistical analysis

A descriptive analysis of the characteristics of all the studies included in the systematic review was carried out, and a meta-analysis was subsequently performed. The articles that were included in the meta-analysis were stratified in two groups according to the source of the sample: data from the general population or from health registries/medical surveys. In turn, articles from the general population were stratified depending on the duration of opioid treatment: long-term (commonly defined as over 3 months ⁸⁴) or short-term (less than 3 months) and depending on the type of pain: general CNCP or chronic low back pain (CLBP). The articles with data from health registries/medical surveys were stratified depending also on the type of pain: general CNCP, fibromyalgia or musculoskeletal conditions (which include musculoskeletal pain, osteoarthritis and CLBP, following The International Classification of Diseases ⁸⁵. Studies performed in populations older than 65 years ⁸⁶, those that could not be compared with any other study, such as those focused on a specific type of pain ^{87,88} or from specific sample source ^{89,90}, or those focused on visits rather than the patients (with the potential overlapping of the records of the patients) ^{91,92} were excluded from the meta-analysis.

From the studies included, the summary measure (prevalence of opioid use, defined as the number of subjects who take opioids divided by the number of individuals with CNCP) was calculated with 95% confidence intervals (CI). Studies were weighted according to the prevalence effect size and the inverse of the study variance.

The heterogeneity between the studies was determined by the DerSimonian and Laird method with Cochran's Q statistic. As heterogeneity was observed in all the study subgroups, random effects models were performed, which considers the variability of the results due to the differences between the studies. The proportion of total variability due to the heterogeneity of

the studies was estimated using the I^2 values. The results of the meta-analysis are presented in forest plots. To assess the potential publication bias in groups with three or more studies, a funnel plot, along with Begg's rank correlation and Egger's weighted regression methods, were used. A two-tailed $p < 0.05$ was considered indicative of a statistically significant publication bias.

Finally, a sensitivity analysis was carried out in the groups with three or more studies to determine the influence of each of the studies on the overall estimate of the effect, and therefore the robustness or stability of the final measurement obtained, through influence graphs. The data were analyzed using Comprehensive Meta-Analysis Software Version 3.0 (Biostat, Englewood, NJ, USA).

Study 2. The evolution of opioid-related mortality and potential years of life lost in Spain from 2008 to 2017. Differences between Spain and the United States.

Study design and population

A descriptive study using the retrospective annual data from 2008 to 2017 in the Spanish and US general populations. It is based on the methodology previously used by Gomes et al ⁶⁹ in the USA to compare populations.

Procedure and Instruments

Information on the population and Opioid Related Death (ORD) stratified by age and sex was obtained from the Centers for Disease Control and Prevention (CDC) WONDER Multiple Cause of Death Database for the USA ⁹³, and the Spanish National Statistics Institute (INE) ⁹⁴. The INE keeps the "statistics of deaths according to the cause of death" ⁹⁵ following the criteria established by the WHO in the International Classification of Diseases (ICD-10) ⁹⁶. This statistic provides information on mortality according to the basic cause of death and its distribution by sex and age, among other factors. A similar methodology is used by the CDC.

From these data, and according to the ICD-10 codes ⁹⁶, we retrieved information on ORD specifically due to accidental poisoning (X40–X44), intentional self-inflicted poisoning (X60–X64), aggression (X85), and poisoning of undetermined intent (Y10–Y14).

Statistical Analysis

For each year (from 2008 to 2017), we report stratified (by sex and age) data on the number of ORD, crude and standardized rates of ORD per 10^5 inhabitants, years of life lost (YLL), YLL per 10^4 inhabitants, and the number of deaths by type of opioid-related death. The crude rate of ORD is defined as the quotient between the number of ORD and the total population, expressed

in terms of number of deaths per 10^5 inhabitants. YLL are defined as the sum of the remaining years that a person who has prematurely died due to opioids has not lived; that is, the sum of the difference of life expectancy and the age of death of each person who has prematurely died due to opioids. Type of opioid-related death is a qualitative variable classifying the deaths by accidental poisoning, intentional self-inflicted poisoning, aggression, and poisoning of undetermined intent. The data presented are tabulated in absolute terms and crude rates. We report the number of deaths by type of death and year in Spain in bar plots, for the total population, and for men and women separately.

The evolution over time of the standardized rates of ORD among the total population, men and women is presented in a line chart for both Spain and the USA. For this comparison, we standardized the data taking into account the different distribution of the two populations by ages. For this standardization, the direct method was used: the rate of each stratum in each population was applied to the world standard population provided by the WHO ⁹⁷ to obtain data on the expected deaths, which were subsequently added and divided by the total standard population to obtain the standardized rates per 10^5 inhabitants. We report these standardized rates in a line chart. All the analyses and figures were performed using the Excel 2016 software.

Study 3. Opioids in the Treatment of Pain. Beliefs, Knowledge, and Attitudes of the General Spanish Population. Identification of Subgroups Through Cluster Analysis

Study design and participants.

A cross-sectional study carried out on a representative sample of the general adult population in Spain.

Sampling Method

The eligible population was obtained using a multistage stratified sampling method. The Spanish territory was divided into eight strata or areas based on geographical and historical boundaries. For each stratum, 20 municipalities were randomly selected, taking into account the Spanish rural/urban ratio of 25:75, and considering municipalities with <10,000 inhabitants as rural and those with >10,000 inhabitants as urban areas. The total number of subjects required for the study was distributed in proportion to the size of each municipality and according to the sex and age distribution of the population (18 to 44, 45 to 64 and 65 or over). The exclusion criteria were individuals younger than 18 years, lack of a landline telephone at home, or the inability to respond to the questionnaire.

Sample Size

The sample size was determined based on the study of Schiller et al.⁹⁸, in which it was estimated that 50% of subjects were afraid of taking morphine. A confidence level of 95% and a precision level of 5% were set. The required sample size was established at 1,155 subjects. The amount of randomly-selected telephone numbers was three times that of the required sample size, in anticipation of non-response.

Procedure and Instruments

Data were collected via a computer-assisted telephone interview using the Skype and the SurveyMonkey platforms, whereby the interviewers recorded the data while the interview was being conducted.

Survey Structure and Topic

The survey was structured in six blocks of questions:

The first block was designed to obtain personal information; the second block was related to the respondents' beliefs about opioids, and in this case the information was collected from an open-ended question in which the interviewees were asked what was the first thing that came to mind when they heard the word opioid; the third block revealed the level of the respondent's contact with opioids and their knowledge of them; the fourth explored the fears (side effects, death, becoming an addict, not achieving the desired results, and death) related to the intake of opioids; the fifth block collected the opinions of the responder regarding this type of treatment (tolerance, dependence, and severity of the disease); and the sixth addressed the responders' attitude toward these drugs. This attitude was obtained by means of a question that asked whether the respondent would agree to treatment with this medication if their doctor prescribed it. The questions that set out to collect information about beliefs, fears, and opinions were assessed using a five-point Likert scale (not at all, a little, some, quite a lot, and a lot).

Statistical Analysis

A descriptive analysis was performed of the variables studied, showing the frequency, central tendency, and dispersion. In addition, a hierarchical cluster analysis was performed to establish groups of individuals or patterns according to the subjects' opinions, fears, knowledge, level of contact, and attitudes toward opioids. The Euclidean distance between the groups and cluster formation criteria were used. Subsequently, the differences between the groups were analyzed

using Chi-squared tests. In addition, a multinomial logistic regression model was established to determine the factors associated with each of the groups previously identified in the cluster analysis. The covariates included in this model were the significant variables identified in the bivariate analysis.

Study 4. *Living with opioids: A qualitative study with patients with chronic low back pain.*

Study design

A qualitative study in which data were collected through 15 semi-structured interviews. Individual interviews were analyzed by qualitative content analysis as applied in health sciences research ⁹⁹.

Participants and Data collection

Recruitment and data collection were conducted from April to October 2018. The participants were recruited from the Pain Clinic in Hospital Puerta del Mar. Inclusion criteria for the study were: adults suffering from chronic non-malignant low back pain and receiving long-term treatment (over three months) with opioids. Patients taking opioids for less than three months or with a pain origin other than chronic non-cancer low back pain were not included.

All the patients were recruited after a routine physical evaluation in their medical visit to the Pain Clinic. Previously, their medical data, including information on prescribed medications from the records, were evaluated and discussed by the clinician and interviewer. If the person met the inclusion criteria after an analysis of their medical records and their medical visit and physical evaluation, the practitioner explained to him or her the aim of the study. All eligible patients were approached by the physician. After this initial approach by the physician, the interviewer met the potential participant and they went to a quieter place in a clinical setting for the interview, before which the participant was shown a letter with more comprehensive information about the study and its aim. The participants were left alone to read and think carefully before giving their written informed consent. When they finished reading it, they had the opportunity to ask questions about the study, after which the interview took place. Individual, semi-structured, qualitative interviews following a guide were conducted in Spanish. The guide was based on open-ended questions developed with guidance from the literature regarding chronic pain experiences and factors associated with the use of opioids. Aspects related to the origin of their pain, opioid belief, information received about treatment, opioid experience, their family and social support were also of particular interest. If a specific topic that was not included in the first version of the interview guide came to light spontaneously in a

specific interview, it was added and asked in the subsequent interviews. Interviews were audio-recorded, transcribed verbatim and anonymized. All names used are pseudonyms. We conducted interviews until experiences were described that were very similar experiences those in earlier interviews.

Analysis

We adopted a constructionist perspective. We analyzed all the interview transcripts following qualitative content analysis as described by Graneheim and Lundman ⁹⁹. The data analysis was inductive, and thus the category construction was data-driven; no initial hypothesis guided the preliminary coding and subsequent development of categories. However, in the analysis of the results presented in the Discussion section of this paper, we followed the biomedicalization framework.

Interview transcripts were entered into Atlas.ti 1.0.16 to support the coding process. At the beginning of each interview transcript, a brief log of the interview was written, including information about the time, duration, and the feelings and perceptions of the interviewer during the conversation in order to help with the analysis process. The researcher who conducted the interviews transcribed them verbatim.

To carry out the qualitative content analysis, two researchers read the transcripts independently and assigned codes line-by-line to meaningful pieces of the interview transcripts. Then, the researchers met to compare and refine codes, which were then grouped into categories. The material was grouped into three key categories, which were further validated after re-analysis of all the interviews. Coding maps were used to help with the code grouping and the analysis of relationships between the emerging categories and codes. In the last step, an overarching theme involving these three categories was identified. The analysis was conducted in Spanish and quotes were chosen from this material to be translated into English. All the authors understand both languages and, thus, were able to participate in the whole analysis process.

Our positions as researchers have continuously been discussed in relation to ethical considerations and questions about responsibility. In line with Graneheim and Lundman (2004) ⁹⁹, we argue that, in qualitative content analysis, interpretation involves a balancing act of providing interpretation while at the same time making sure that our interpretations remain always grounded on the data. By providing a thorough explanation of the analytical process, our intention is to allow the reader to assess the usefulness and transferability of the study.

RESULTS

STUDY 1

Prevalence of therapeutic use of opioids in chronic non-cancer pain patients and associated factors: a systematic review and meta-analysis.

Helena De Sola*; *María Dueñas; Alejandro Salazar; Patricia Ortega-Jiménez; Inmaculada Failde*

*The author of this thesis contributed to this work by performing the search strategy, studies selection, analysing the data, and was mainly responsible for writing the manuscript.

ABSTRACT

Purpose: To determine the prevalence and factors associated with the use of opioids among patients with Chronic Non-Cancer Pain (CNCP).

Methods: A systematic review and meta-analysis. Comprehensive literature searches in PubMed and SCOPUS databases. Original papers published between 2009 and 2019 with a cross-sectional design were included. Protocol registered in the International Prospective Register of Systematic Reviews (PROSPERO) with reference number: CRD42019137990

Results: Out of the 1062 potential articles found, 23 studies fulfilled the inclusion criteria. In the general population, the prevalence of long-term opioid use was 2.3% (95%CI:1.5%-3.6%), the prevalence of short-term opioid use was 7.3% (95%CI:4.3%-11.9%), and among people with chronic low back pain was 5.8% (95% CI:0.5% - 45.5%). The prevalence of opioid use among patients from the health records or medical surveys was 41% (95%CI:23.3%-61.3%). Finally, in patients with musculoskeletal pain, the prevalence was 20.5% (95%CI:12.9%-30.9%) and in patients with fibromyalgia, 24.5% (95%CI:22.9%-26.2%). A higher prevalence of opioid use was observed among men; younger people; patients receiving prescriptions of different type of drugs; smokers and patients without insurance or with noncommercial insurance. In addition, non-white and Asian patients were less likely to receive opioids than non-Hispanic white patients.

Conclusions: The prevalence of opioid use among patients with CNCP varies depending on the duration of treatment and the population analyzed, with higher prevalence in clinical studies based on health registries and occasional users. Age, race, and the access to and the characteristics of the health service delivery system are the factors most related to opioids use.

Keywords: Chronic pain, Meta-analysis, Opioids, Prevalence, Systematic review.

INTRODUCTION

Chronic pain (CP) is a major public health concern ¹ that is associated with disability, distress, and a decrease in the quality of life of affected individuals ². The prevalence of moderate to severe CP in the general adult population ranges from 2% to 55% in different countries ³⁻⁵, with an estimated global annual cost over US\$245 billion ⁶.

It has been recognized that the physiopathology of CP involves complex interactions between physical, psychological, and social factors, and that its adequate management needs a multidisciplinary approach ⁷. However, pharmacological therapy remains a mainstay for treating these patients ⁸, opioids being one class of pharmacotherapies highly prescribed to modulate pain ⁹.

Opioid therapy in CP has recently received a growing interest related to the increased use observed in these patients ¹⁰⁻¹². This situation is of particular concern in patients with chronic non-cancer pain (CNCP), where the evidence of its benefits may be less robust than that observed in patients with acute or cancer pain ¹³⁻¹⁵. The length of opioid therapy is also important to patients' benefits, since prescription opioids may be appropriate for short-term pain relief, but long-term opioid therapy (LTOT) cannot be associated with improvements in pain or function ¹⁶.

Furthermore, it has been shown that the introduction of high-dose and extended-release oral tablet formulations of opioids has increased the total prescriptions among CNCP patients ^{10,14,17}, becoming an important social problem in some countries such as the United States ^{18,19}. The differences in opioid prescribing patterns have been related to age, gender, ethnicity, pain diagnosis, number of total medications, payment type, physician specialty, and patient relationship with provider ²⁰. Thus, it is necessary to collect and summarize the information published with valid and reliable results about the therapeutic use of opioids for CNCP in different countries. Additionally, it is necessary to take into account the length of the treatment and factors associated with it in order to produce international estimates. To this end, we carried out a systematic review of the literature to know the prevalence of the therapeutic use of opioids among patients with CNCP and, as a second aim, the analysis of the factors associated with their use. We also performed a meta-analysis of the prevalence of the therapeutic use of opioids to summarize the information obtained.

METHODS

Protocol and registration

The present systematic review and meta-analysis was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) statement ²¹. The study protocol was registered in the International Prospective Register of Systematic Reviews (PROSPERO) with reference number: CRD42019137990.

Design of the study

Systematic review of the current literature and meta-analysis.

Search strategy

A systematic search strategy was performed in the PubMed and SCOPUS databases. Original cross-sectional studies published from 2009 to 2019 in English or Spanish were included. The terms/keywords of interest were “opioid”, “analgesic”, and “pain”. The terms were combined with the tag for searching in the title, abstract and keywords. The search terms and search strategies were adapted to each database (Supplemental material, S1).

Once the search strategies for both databases were executed, we imported all the references found into the Covidence online tool ²². The process of duplicate removal, screening, data extraction and risk of bias analysis were performed by this web-based systematic review tool.

Eligibility criteria

According to the predefined inclusion criteria, an article was selected when its main aim was to determine the prevalence of the use of opioids in CNCP humans (all ages), provided these data were shown within the paper or it was possible to calculate them from it. Articles related to CNCP located in specific body regions (e.g. musculoskeletal CP) were also included. Thus, the term “chronic non-cancer pain” was not included in the search strategy in order not to limit the searches to studies presenting only data from general CNCP. The criterion to define CNCP and the specific body regions where each article is focused on are specified in table 2.

Studies including patients with cancer pain, focusing on the opinions or attitudes of physicians about opioid prescription or on the disorders derived from their consumption were excluded (Supplementary material S2).

Study selection

Two authors (MD and HDS) independently screened the title and abstract of all of papers. Shortlisted studies were then analyzed in depth according to the inclusion criteria and their reference lists were also revised to identify studies that could be included in the review. The quality of the studies was assessed following the Critical Appraisal Checklist for Analytical Cross-sectional studies from the Joanna Briggs Institute ²³. This checklist consists of 8 items regarding inclusion criteria, study sample and setting, exposure measured, standard criteria for measurement, confounding factors, strategies to deal with confounders, outcomes measured and statistical analysis (Supplementary material S3). Each item was assessed as “yes”, “no”, “unclear” or “not applicable”. For standardization, we considered “yes” as low risk of bias, and “no” and “unclear” as high risk of bias. Overall, low risk of bias (i.e., high quality study) was considered when a study accumulated at least 5 items answered as “yes”. Studies assessed as ‘yes’ in <5 items were categorized as high risk of bias (i.e., low quality study). Any disagreements regarding the suitability of a study were resolved after appraisal by a third author (AS).

Data extraction

From the selected papers, information was extracted about the primary aim of the study, characteristics of the population studied, the sample source, sample size, method for data retrieval, and response rate (Table 1). Likewise, the definition of CNCP considered in each article, prevalence of CNCP in the population studied, prevalence of opioid use, the method for obtaining this prevalence data, and the factors associated with opioid use were collected (Table 2).

Statistical analysis

A descriptive analysis of the characteristics of all the studies included in the systematic review was carried out, and a meta-analysis was subsequently performed. The articles that were included in the meta-analysis were stratified in two groups according to the source of the sample: data from the general population or from health registries/medical surveys. In turn, articles from the general population were stratified depending on the duration of opioid treatment: long-term (commonly defined as over 3 months ¹⁶) or short-term (less than 3 months) and depending on the type of pain: general CNCP or chronic low back pain (CLBP). The articles with data from health registries/medical surveys were stratified depending also on the type of pain: general CNCP, fibromyalgia or musculoskeletal conditions (which include musculoskeletal pain, osteoarthritis and CLBP, following The International Classification of

Diseases²⁴) (Table 3). Studies performed in populations older than 65 years²⁵, those that could not be compared with any other study, such as those focused on a specific type of pain^{26,27} or from specific sample source^{28,29}, or those focused on visits rather than the patients (with the potential overlapping of the records of the patients)^{30,31} were excluded from the meta-analysis.

From the studies included, the summary measure (prevalence of opioid use, defined as the number of subjects who take opioids divided by the number of individuals with CNCP) was calculated with 95% confidence intervals (CI). Studies were weighted according to the prevalence effect size and the inverse of the study variance.

The heterogeneity between the studies was determined by the DerSimonian and Laird method with Cochran's Q statistic. As heterogeneity was observed in all the study subgroups, random effects models were performed, which considers the variability of the results due to the differences between the studies. The proportion of total variability due to the heterogeneity of the studies was estimated using the I^2 value. The results of the meta-analysis are presented in forest plots. To assess the potential publication bias in groups with three or more studies, a funnel plot, along with Begg's rank correlation and Egger's weighted regression methods, were used. A two-tailed $p < 0.05$ was considered indicative of a statistically significant publication bias.

Finally, a sensitivity analysis was carried out in the groups with three or more studies to determine the influence of each of the studies on the overall estimate of the effect, and therefore the robustness or stability of the final measurement obtained, through influence graphs.

The data were analyzed using Comprehensive Meta-Analysis Software Version 3.0 (Biostat, Englewood, NJ, USA).

RESULTS

The search identified 1062 potential articles. After the selection process (Figure 1), 24 suitable articles were identified. Three more studies obtained by the additional search strategies (citation search) were added. Results of the risk of bias, measured with the Critical Appraisal Checklist for Analytical Cross-sectional studies, are shown in Supplementary Material S3. It shows that 23 articles had low risk of bias (i.e., high quality study). Out of these 23 articles, eight had been performed in the general population^{27,30,32–37}, and fifteen in patients with CNCP from medical surveys or medical records^{25,26,43–47,28,29,31,38–42} (Table 1). The data were gathered from thirteen countries. Most studies ($n=15$) were restricted to adult populations (18 years or older), whereas one study also included adolescents (≥ 16 years)³², three included children (all ages)^{30,35,39}, and one included only people over 65²⁵. In three studies, the age was not specified.

Thirteen articles were performed in patients suffering from a chronic painful process of specific cause (e.g., musculoskeletal pain)^{27,29,44,46,47,30,31,36,37,40–43}. The reported participation rates in the studies ranged from 37%⁴³ to 84.8%³⁵, but in some instances, the information given by the authors was missing or unclear (Table 1). Chronic pain was defined as pain lasting at least 6 months in four of the included articles^{28,32,33,35}, while in the rest, it was considered as pain lasting more than 3 months. The prevalence of CNCP in the studies performed in the general population ranged between 6.8%³⁸ and 35.7%³⁴ (Table 2).

Prevalence of opioid use

Out of the eight articles set in the general population, two distinguished between short-term or occasional opioid users and long-term or persistent opioid users. The prevalence was higher in those in which the use was short or occasional (3.9% to 12.3% vs. 1.8% to 2.9%)^{32,33}. Three articles (out of eight carried out in the general population) were focused on CLBP, and the prevalence ranged from 1.6%³⁶ to 18.8%³⁷. Another article retrieving data from five countries was focused on osteoarthritis, being the total opioid prevalence 16.7%²⁷.

In the articles analyzing the population from medical registries or medical surveys, the prescription of opioids was variable, being 32.7% in patients that were attended to General Practices³⁹ or 64.4% in patients attended in a pain center²⁸. In the studies in patients suffering a specific pain condition, the use of opioids ranged from 13.1% to 20.8% in the case of musculoskeletal pain^{31,40}, from 12%⁴¹ to 22% in osteoarthritis⁴⁴ and from 8.4%⁴⁷ to 22.4% in fibromyalgia⁴². The highest opioid use prevalence was 81.1%, in a study performed in a nursing home with people ≥ 65 years²⁵ (Table 2).

Factors associated with the use of opioids

Seven of the articles included in the review analyzed the factors associated with the use of opioids, observing a greater use of these drugs in men^{33,38}, in young people^{31,33,38}, in patients receiving prescriptions of different kind of drugs³³, in smokers⁴³, and in patients without insurance or with noncommercial insurance, especially Medicaid and Medicare, versus those with private insurance^{31,38,45} (Table 2).

The use of opioid was also related with the physician. Patients who had been followed by a physician, had higher odds of being prescribed an opioid than naive patients⁴⁵. Moreover, if the primary care physician was trained in complementary medicine, he/she was significantly less likely to prescribe opioids⁴³.

Additionally, the use was greater in patients with a pain-related disability³⁴ and in those with more CP conditions³⁸. However, patients with a higher score on the Charlson Comorbidity Index (2-3 vs. 0) had lower odds of receiving an opioid³⁸ (Table 2).

Race was related to the use of opioids in two studies, which showed that non-white patients³¹ and Asian patients³⁸ were less likely to receive opioids than non-Hispanic white patients (Table 2).

Results of the meta-analysis

Out of the 23 articles included in the review, 16 were included in the meta-analysis, stratified into six subgroups. Group A^{32,33} included two studies carried out in the general population, with patients with general CNCP, where the duration of the use of opioids was long-term or persistent. Group B³²⁻³⁵ included four studies, also performed in the general population and with patients with general CNCP, but in which the duration of the use of opioids was short-term. Group C^{36,37} included two studies in the general population which analyze patients with CLBP who had been prescribed opioids. Group D^{38,39,45} consisted of three studies that included patients with general CNCP from health registries who had been prescribed opioids. Group E^{40,41,43,44,46} included five studies with patients from medical surveys, with musculoskeletal conditions (including musculoskeletal pain, osteoarthritis and CLBP) and who had been prescribed opioids at the moment of the study. Finally, group F^{42,47} included two studies of fibromyalgia patients from medical surveys who had been prescribed opioids (Table 3).

The characteristics and results of the meta-analysis (heterogeneity tests, estimated prevalences with 95% CI, relative weights and tests for publication bias) of the studies included in each of the six subgroups are shown in Table 3 and Figure 2, respectively.

As shown in Table 3, we found heterogeneity between the groups, demonstrating a marked variability among the estimates ($I^2 > 77$, $p < 0.05$, in all cases). Therefore, the model used for the estimations of the summary prevalence was the random effects model.

Among the results obtained, it is noteworthy that in the general population, the prevalence of long-term opioid use among patients with general CNCP was 2.3% (95% CI: 1.5% - 3.6%), the prevalence of short-term opioid use was 7.3% (95% CI: 4.3% - 11.9%), and the prevalence in CLBP was 5.8% (95% CI: 0.5% - 45.5%). The prevalence among patients from health registries or medical surveys was 41% (95% CI: 23.3% - 61.3%) in patients with general CNCP. The prevalence in patients with musculoskeletal conditions was 20.5% (95% CI: 12.9% - 30.9%) and in patients with fibromyalgia was 24.5% (95% CI: 22.9% - 26.2%) (Table 3 and Figure 2).

Figure 3 shows the funnel plot for meta-analysis of subgroups B, D and E, suggesting no evidence of publication bias. Neither Egger's test nor Begg's test were statistically significant for the publication bias (Table 3).

Finally, Figure 4 shows the result of the sensitivity analysis for subgroups B, D and E, indicating in the three cases that none of the studies included would substantially change the overall result of the study summary prevalence if the studies were eliminated from the meta-analysis. This finding indicates that the results are robust, since none of the studies exerted a great influence on the final result.

DISCUSSION

This paper analyzes the information published about the prevalence of the use of opioids in patients with CNCP and examines the factors associated with their use.

The results reveal that there were differences in the prevalence of the use of these drugs depending on the length of the treatment (2.3% in long duration or 7.3% in occasional use)^{32,33}. It was also observed that when the information comes from health registries, the prevalence is much higher than in the general population, and more variable depending on the specialty of the health center.

The lower prevalence found in patients with longer treatments seems reasonable if we take into account, on the one hand, the prescribers' concern about the risk of addiction and the improper use of these drugs by some patients⁴⁸ and, on the other hand, the treatment dropout, possibly due to the appearance of analgesic tolerance, induced hyperalgesia, and side effects frequently associated with these drugs^{49,50}.

Likewise, the results observed in the studies based on health registries could be explained because these patients are usually treated in specialized pain units by physicians with expertise in pain management, who are more likely to prescribe more opioids than doctors in other specialties^{39,51}. Regarding the specific pathologies, the prevalence in patients with musculoskeletal conditions was 20.5% and in patients with fibromyalgia 24.5%^{38,52}. Musculoskeletal conditions are one of the most common causes of pain^{53,54}, and the use of weak opioids is recommended, since there is strong evidence that weak opioids relieve pain and disability in the short-term in these patients⁵⁵. However, in the case of Fibromyalgia, current treatment guidelines do not recommend opioids for its symptom management⁵⁶. Our findings suggest that, despite a lack of scientific support of opioid treatment in people with fibromyalgia, possibly because of an inability of opioids to target the pathophysiological processes involved in

this central sensitization syndrome ⁵⁷, clinicians are nevertheless prescribing them for symptom management in this patient population.

In the analysis of the factors associated with the use of opioids, it was observed that younger individuals showed greater use. One explanation could be that opioids are not always recommended for the elderly population, due to a higher probability of liver or kidney dysfunction, greater risk of respiratory depression, drug interactions, organ dysfunction, co-morbidity and side effects, such as constipation, drowsiness or sedation, that can have more serious consequences in this population ³⁸. Likewise, it has been shown that medical personnel sometimes underestimate pain in the elderly, which leads to a lower prescription of opioids in these patients ^{58,59}.

Regarding the race, different studies have shown that the pain experience is different according to the ethnic group. This finding has been attributed to different responses to painful stimuli and the different coping strategies for managing pain observed in these patients ^{31,38,60,61}. Additionally, according to Anderson et al. ⁶², there are other factors that could influence these differences, such as selective care and differences in the process of evaluation and allocation of treatment according to the ethnic group of the patient.

Another factor to consider is the type of care received by the patient. The type of medical insurance can influence the manner of approaching the pain and consequently determine the use of opioids. It has been shown ⁶³ that patients with private insurance obtain better results than patients with public coverage since, in addition to the fact that the care is more immediate, the multidisciplinary approach is more common and produce better results decreasing the use of analgesic treatment ⁶⁴. In this vein, Rodondi et al ⁴³ highlighted that the training of the physician in complementary medicine also influences on prescribing less opioid treatments, since specialized in integrative and complementary medicine could help inform and guide patients about the most effective treatment options, their potential interactions with conventional therapies, and their side effects.

Finally, it would be reasonable to think that in those studies where the prevalence of CP is higher, the use of opioids would also be greater ⁶⁵. However, when we compare the results from different countries, this hypothesis is not confirmed, as the factors that seem most important are the method of data collection and the characteristics of the population included in the studies ^{35,66}.

Some limitations of this review should be noted. It is worth mentioning that three of the subgroups in the meta-analysis included only 2 studies. The minimum number of studies to

include in a meta-analysis has been previously discussed in the literature, without clear agreement ^{67–69}. Some researchers consider that a minimum of 5 studies are desirable, or even required. Others argue that, as long as the studies meet the quality criteria and statistical requirements, the meta-analysis can be carried out, as it is just a statistical combination of the results. The number of studies in the literature on a topic do not depend on us, and the lack of studies on these topics (in our case, studies carried out in general population focused on the prevalence of the use of opioid in long-term; in general population focused on the prevalence of the use of opioid in CLBP; and from health records or medical surveys focused on the use of opioid in fibromyalgia) is itself a relevant result, and it shows the need for further research on the topics. Of course, the number of studies has a direct impact on the statistical power and precision, but if those few studies are relevant and their quality is high, we believe that it is worth drawing conclusions from them. At this vein, Terri D. Pigott ⁶⁷, argued that the quick answer for the minimum number of studies is two, but recommend to compute the statistical power a priori, “using assumptions about the size of an important effect in a given context, and the typical sample sizes used in a given field”. Finally, Valentine et al. ⁶⁹ state that a meta-analysis is always the best option to synthesize information (even if we have few studies), as other alternatives “are likely to be based on less defensible assumptions and on less transparent processes”. Consequently, we decided to perform these three meta-analyses which, however, need to be interpreted with caution, given the limited statistical power.

As a strength of the study, we would like to highlight its novelty since, to the best of our knowledge, no systematic review and meta-analysis on the prevalence of the therapeutic use of opioids has been published previously.

CONCLUSIONS

This study shows that the prevalence of opioid use in patients with CNCP varies depending on the duration of treatment and the population analyzed, with higher prevalence in clinical studies based on health registries and occasional users. Likewise, age, race, and the access to and the characteristics of the health service delivery system are the factors most related to the use of opioids.

Table 1. Characteristics of the studies included in the systematic review.

First author, Year	Primary aim	Population	Sample source and timeframe	Method for data retrieval	N	Response Rate
<i>Rodondi P. et al. 2019</i>	To investigate among primary care patients and their physicians in western Switzerland the prevalence of use, perceived usefulness, and communication about treatments for chronic or recurrent low back pain (CLBP) including complementary medicine.	Patients with CLBP recruited during regular medical appointment. (≥18 years)	Primary care physician in western French-speaking area of Switzerland from November 1, 2015, to May 31, 2016	Self-reported questionnaires	499	37%
<i>Callhof J. et al. 2019</i>	To analyze factors associated with the burden of osteoarthritis (OA), taking the pattern of joint involvement into account.	Patients with OA of the knee or hip or with polyarthritis (30–79 years)	German statutory health insurance database (BARMER). Year 2016	Survey and claims data	8,995	42%
<i>Lin H-C et al. 2019</i>	To examine how prescription drug monitoring programs interstate data sharing with bordering states was associated with patients being prescribed opioids for non-cancer Chronic Pain (CP) treatment.	Adult patients with non-cancer CP (≥18 years).	National Ambulatory Medical Care Survey (NAMCS) 2014	The NAMCS	Weighted N=66,198,751; unweighted N=2846	

<i>van den Driest J. J et al. 2019</i>	To examine the analgesic used by patients with OA related pain and how the analgesics are used in the preceding month	Patients with rheumatic diseases (Age not specified)	The panel of the Dutch Arthritis Foundation	Online questionnaire	842	56%
<i>Shmigel A. et al. 2018</i>	To examine patterns of drugs prescription among Americans with CLBP in a nationally representative, community-based sample.	A representative sample of US adult population (aged 20–69)	The National Health and Nutrition Examination Survey (NHANES). 2009–2010.	Home-based interviews with pill bottle verification to capture prescribed medications for CP.	5,103	
<i>Scala E. et al. 2018</i>	To evaluate the level of readiness to practice different types of active self-care among chronic pain patients.	Patients with CP. (≥18 years).	Patients seeking care at the Pain Center University Hospital, Switzerland between June 2013 and March 2015	Self-administered questionnaire.	639	41.9%
<i>Sites B D. et al. 2018</i>	To understand the relationship between prescription opioid use and satisfaction with care among adults who have musculoskeletal conditions	Patients with musculoskeletal conditions (≥18 years).	Nationally representative data from the 2008-2014 Medical Expenditure Panel Survey (MEPS)	5 rounds of telephone interviews over a 30-month period and questionnaires.	19,566	
<i>Knoop J. et al. 2017</i>	To describe the use of analgesics; and to determine factors that are related to analgesic use in patients with knee and/or hip OA referred to an outpatient center	Patients referred to an outpatient center with knee and/or hip OA diagnosed (Age not specified)	Amsterdam Osteoarthritis (AMS-OA) cohort in an outpatient center (Reade, center for rehabilitation and rheumatology, the Netherlands) from	Questionnaires	656	

December 2009 to July
2016

<i>Miller A. et al.</i> 2017	To estimate the prevalence of CP and analgesia use in the Australian population by age and sex; the severity of pain in the population with CP by sex; and the distribution of recent pain severity in those using analgesia by age and sex.	Representative sample of Australian population. (All ages).	The Australian Bureau of Statistics (ABS)	Face-to-face interviews conducted by trained ABS interviewers in participants' homes	n=20,426 participants from 15,565 private residences. 1 adult and 1 child aged 0 to 17 years (if applicable) in each participating household.	84.8%
<i>Romanelli R J. et al.</i> 2017	To evaluate opioid prescribing in an ambulatory setting among patients with chronic non cancer pain (CNCP)	Adult patients with CP with a medical record in the Electronic Health Record system (EHR) (≥18 years).	Using Sutter EHR (Community-based open-network healthcare system in northern California)	The EHR	1,784,114	
<i>Fain K M. et al.</i> 2017	To quantify prescription analgesic use of elderly nursing home residents with persistent non-cancer pain and to identify individual and facility traits associated with no treatment.	Elderly nursing home residents with persistent noncancer pain. (≥65 years)	Individuals residing in a Nursing Home in U.S. at any time between December 2007, and November 2008	The Minimum Data Set; the Online Survey, Certification, and Reporting (OSCAR) database; and Medicare Part D	2.99 million individuals	
<i>Gouveia N. et al.</i> 2017	To analyze and characterize the intake profile of pain-relief drugs in a population-based study of adults with chronic low back pain (CLBP).	Adult Portuguese population with self-reported active CLBP (>18 years)	Households selected by random route methodology	Face-to-face interview.	10,661	

<i>Ahn Y-J. et al. 2016</i>	To assess medical care and costs of the 3 highest prevalence lumbar disorders -non-specific low back pain (nLBP), intervertebral disc disorder (IDD) and spinal stenosis (SS)- to provide basic information for standards of appropriate management.	Patients included in 2011 Korean Health Insurance Review and Assessment Service (HIRA) (All ages)	National Health Insurance National Patient Sample data provided by HIRA. Year 2011	2011 HIRA National Patient Sample (NPS)	1,375,842	
<i>Birke H. et al. 2016</i>	To examine the trends regarding the prevalence of CNCP, dispensed opioids, and concurrent use of benzodiazepine (BZD)/ BZD-related drugs in the Danish population	Participants with chronic pain. (≥16 years)	The Danish National Cohort Study (DANCOS). Years 2000, 2005, 2010 and 2013.	In 2000 and 2005, face-to-face interviews and self-administered questionnaire. In 2010 and 2013, postal or web questionnaire	16,684 in 2000 10,916 in 2005 25,000 in 2010 25,000 in 2013	63% in 2000 51% in 2005 61% in 2010 57% in 2013
<i>Wand B. M. et al. 2016</i>	To present the outcomes of a comprehensive evaluation of the psychometric properties of the Fremantle Back Awareness Questionnaire (FreBAQ) and explore the potential relationships between body perception, nociceptive sensitivity, distress, and beliefs about back pain and the contribution these factors	People with axial CLBP (between 18 and 70 years)	From 2 metropolitan hospitals in Western Australia, private metropolitan physiotherapy clinics, pain management and general practice clinics. Also, via multimedia advertisements circulated throughout the general community Western Australia	Self- administered questionnaire and a combination of clinical bedside tests and laboratory tests	251	

might play in explaining pain and disability

<i>Vincent A. et al. 2015</i>	To evaluate the problem of multiple chronic conditions and polypharmacy in patients with fibromyalgia.	Patients with fibromyalgia. (≥21 years)	Patients identified via the Rochester Epidemiology Project (REP) in Olmsted County, Minnesota. Between January 2005 and December 2009		1,111
<i>Laroche M. R. et al. 2015</i>	To characterize trends in opioid prescribing and co-prescribing of sedative hypnotics at acute and chronic musculoskeletal pain visits from 2001 to 2010.	Patients with musculoskeletal pain. (≥18 years)	Combining the National Ambulatory Medical Care Survey & National Hospital Ambulatory Medical Care Survey.	Data collection was carried out by physicians, hospital staff, or Census field representatives.	35,302
<i>Marschall, U. et al. 2015</i>	To determine the prevalence and the demographic and medical predictors of Long-Term Opioid Therapy (LTOT), of high dose of LTOT and of abuse/addiction of prescribed opioids in a cohort of insureds with CNCP of a large German statutory health insurance.	Persons insured by the German statutory medical health insurance. (Age not specified).	From the records of outpatient (Association of Statutory Health Insurance Physicians bills) and inpatient care (hospital bills) of persons insured by the German statutory medical health insurance plan Barmer GEK January 2012 and December 2012.	The Barmer GEK.	870,000

<i>Kingsbury S. R et al. 2014</i>	To examine the impact of peripheral joint OA across five large European countries and how people with OA use pharmacotherapies.	The general population using the Internet panel maintained by Lightspeed Research. (≥18 years)	Data were derived from the 2011 five European countries (5EU) National Health and Wellness Survey (NHWS)	Respondents were emailed a link to the survey to complete on their own. ≥65-year-old population were recruited by telephone and they had the choice to complete the interview on the phone.	57, 512: France: n=15000 Germany: n=15001 Italy: n=7500 Spain: n=5011 UK: n=15000	
<i>Fredheim O. M. S. et al. 2014</i>	To know the prevalence of persistent opioid use among people in the general population with self-reported CNCP	All inhabitants in the county of Nord-Trøndelag in Norway (≥20 years).	Linkage of the National Norwegian prescription database and the Nord-Trøndelag health study 3 2006 to 2008	2 Postal questionnaires and a physical examination.	45,837	
<i>Azevedo L.F. et al. 2013</i>	To describe the prevalence and factors associated with opioid use in subjects with CP in Portugal and to evaluate satisfaction and self-assessed treatment effectiveness.	A representative sample of the adult Portuguese population (≥18 years)	Random digit dialing.	A structured questionnaire conducted by computer-assisted telephone interviews (CATI).	5,094	76% among responding households and 51% among all identified households.
<i>Henderson, J. V et al. 2013</i>	To determine the prevalence of CP, its causes, severity, management, impact on sleep, mood and activity levels, and general practitioner (GP) and patient	Patients attending to General Practice. (All ages)	The BEACH (Bettering the Evaluation And Care of Health), an Australian General Practice program.	Questionnaires were completed by the GP in discussion with the patient, using the combined knowledge of both.	5,793	79%

satisfaction with pain
management.

<i>Häuser W. et al. 2012</i>	To conduct the first European fibromyalgia syndrome (FMS) consumer reports on the effectiveness and side effects of FMS-therapies in routine clinical care.	Members of the self-help organisations with diagnosis of FMS (Age not specified).	From the two largest German FMS-self help organisations and nine clinical institutions. 2010 to 2011	Self-reported questionnaires	1,661
----------------------------------	--	---	--	---------------------------------	-------

Table 2. Prevalence of opioids' use and factors associated to opioid use in chronic pain population.

Author	Pain definition	Prevalence of CP	Method for obtaining the opioids prevalence	Prevalence of opioid use	Factors associated to opioid use in CP patients
<i>Rodondi P. et al. 2019</i>	Chronic Low Back Pain (CLBP) defined as pain lasting or recurring for 3 months or more.	The whole sample had CLBP (N=499)	Self-reported use of assessed therapies	52.5% of the CLBP patients	<ul style="list-style-type: none"> - Current smoking was associated with using opioids (OR=1.8; 95% CI, 1.1–3.1) - Patients from primary care physician who were trained in complementary medicine were significantly less likely to use opioids (OR=0.5; 95% CI, 0.3–0.9)
<i>Callhof J. et al. 2019</i>	Persons with ICD-10- GM (German Modification) diagnoses of Osteoarthritis (OA) in 2014	The whole sample had OA (N=3,564) <ul style="list-style-type: none"> - 758 polyarthrititis (POA) - 959 hip OA. - 399 hip and knee OA - 1,448 knee OA 	Analgesics were identified using ATC codes, counting patients as users if they had ≥1 prescription of the drug in that year.	14.9% of the total OA patients <ul style="list-style-type: none"> - 14% POA. - 14% hip OA. - 22% hip and knee OA - 14% knee OA. 	
<i>Lin H-C et al. 2019</i>	The ICD-9-CM diagnosis codes provided by the NAMCS	The whole sample had non-cancer CP (N=2846)	The electronic health records, including information on prescribed medications	33.1% of the study sample.	<ul style="list-style-type: none"> - Patients aged 25–49 vs. 18–25 years (OR=2.78; 95% CI, 0.93-8.33) - Patients with Medicare (OR=1.56; 95%CI, 1.03-2.38) or Medicaid coverage (OR=2.08; 95%CI, 1.15-3.85) vs. who had private insurance coverage. - Patients being followed by the physician versus naïve patients.(OR=2.33; 95% CI, 1.49-3.57)
<i>van den Driest J. J et al. 2019</i>	Generalized OA was defined as self-reported OA in 3 or more groups of joints	The whole sample had OA (N=842)	Self-reported analgesics used in the preceding month	22% of the patients with OA-related pain	
<i>Shmagel A. et al. 2018</i>	CLBP was defined as self-reported pain in the area between the lower posterior margin of the	13.7% had CLBP (N=700)	Self-reported prescription medications used within the past 30 days	18.8% of working-age Americans with CLBP	<ul style="list-style-type: none"> - Low levels of education: For less than high school (OR=3.07; 95% CI, 1.12–8.39) and for high school or associates' degree (OR=4.17; 95% CI, 1.73 – 10.03) compared with college education

	ribcage and the horizontal gluteal fold on most days for at least 3 months.			<ul style="list-style-type: none"> - <35,000 of annual household income (OR=1.92; 95% CI, 1.19–3.11) vs >65,000 - 2 or more medical comorbidities (OR=3.32; 95%CI, 1.74–6.35) vs none or one
<i>Scala E. et al. 2018</i>	Pain lasting 6 months or more.	The whole sample had CP (N=639). The locations were back (71.4%), lower limb (68.4%), cervical spine (25.8%), an upper limb (25.2%) or a shoulder (23.0%).	Patients were asked whether they used non-opioid painkillers, opioids or dietary supplements 'against pain' during the last six months.	64.6% of the study sample.
<i>Sites B D. et al. 2018</i>	A combination of (ICD-9-CM) codes and patient self-reported data	The whole sample had musculoskeletal pain (N=19,566)	Participant were ask to report prescription medication use and pharmacies were contacted to validate these prescriptions	13.1% opioid users. <ul style="list-style-type: none"> - 29.2% as low-level users (2 to 4 opioid prescriptions) - 28.9% as moderate users (5 to 9) - 41.9% as heavy users. (10 or more)
<i>Knoop J. et al. 2017</i>	Clinical knee and/or hip OA diagnosed, according to the American College of Rheumatology criteria.	The whole sample had OA (N=656)	Patients were asked to list all medication used at that moment	12% use of opioids <ul style="list-style-type: none"> - 6% Tramadol - 3% Codeine - 1%Prednisone - 3% Other
<i>Miller, A. et al. 2017</i>	Self-reported pain which persisted over a 6-month period.	<ul style="list-style-type: none"> - 12.7% of all ages (N=2.8 million) - 15.4% (aged ≥15 years). - 14.6% males - 16.1% females. 	Opioid analgesia use included the use of any type of opioid analgesia over the previous 2-week.	12% males vs. 13.4% females (aged ≥15 years). <ul style="list-style-type: none"> - 15-24 years 17.0%. - ≥85 years and female 29.0%.

Participants were asked for the name or brand of all medication, and they were requested to provide the packages to the interviewer.

<i>Romanelli, R. J et al. 2017</i>	Patients with 2 records of ICD-9 CM, diagnoses for a Chronic Non Cancer Pain (CNCP) condition (pain lasts longer 3 month) at least 30 days apart	6.8% (N=120,481)	The electronic health records, including information on prescribed medications.	<p><u>Received any opioids among all CP Patients:</u></p> <p>- 58.1%</p> <p><u>Short-acting (immediate-release) opioids:</u></p> <p>-57.4%.</p> <p><u>Long-acting opioid:</u></p> <p>-7%</p>	<p>CP Conditions per Patient by CP Category:</p> <p>-Arthritis/joint pain (OR=1.39; 95% CI, 1.36-1.42)</p> <p>-Back/cervical pain (OR=1.07; 95% CI, 1.05-1.09)</p> <p>-Neuropathies/neuralgias (OR=1.65; 95% CI, 1.61-1.69)</p> <p>-Headaches/migraines (OR=1.51; 95% CI, 1.47-1.56), unclassified pain (OR, 1.48; 95% CI, 1.44-1.53).</p> <p>Patient demographic characteristics</p> <ul style="list-style-type: none"> - Older patients (≥ 66 years vs 18-45 years) (OR=0.55; 95% CI, 0.52-0.58) - Those with moderate chronic disease burden (CCI score = 2-3 vs 0) (OR=0.92; 95% CI, 0.88-0.96) - Asians (vs. NonHispanicWhite)(OR=0.37; 95%; CI,0.33-0.40) <p>Patients with higher odds of receiving an opioid were:</p> <ul style="list-style-type: none"> - Men (over women). - Patients with noncommercial insurance, especially Medicaid (OR=2.77; 95% CI, 2.56-3.01) - Patients with more CP conditions (OR=3.27; 95%; CI,3.15-3.40).
<i>Fain, K M., et al. 2017</i>	Moderate to severe daily pain lasting at least 3 months	3.8% (N=18,526) of eligible nursing home residents had persistent pain	An opioid prescription dated within 30 days before or after persistent pain onset.	- 81.1% received an opioid drug (alone or in combination with	

				acetaminophen or prescription NSAID). -16.2% had only opioids prescription.
<i>Gouveia N. et al. 2017</i>	Low Back Pain lasting at least 90 days	10.4% (CI 9.56%; 11.9%) (N=1,487)	According to the national drug agency (INFARMED) classification.	- 1.6% (95% CI 0.9-2.2) among population with Active CLBP
<i>Ahn Y-J. et al. 2016</i>	Patients with a lumbar disorder coded by the Korean Classification of Diseases, adapted from the ICD-10	27% (Patient visiting medical institution with lumbar/spinal diagnostic codes N=371,858)	The use of medications documented in the medical record	2.3% of the total patients with lumbar disorder included for analyses (n=135,561)
<i>Birke H., et al. 2016</i>	Pain lasting 6 months or more.	-18.9% in 2000 - 20.2% in 2005 - 26.2% in 2010 - 26.8% in 2013.	The Danish National Prescription Registry using ATC codes. Long-term, having used at least one prescription/month for 6 months. Short-term having used at least one prescription in the previous year.	Opioid users among individuals with CP <u>Long-term</u> - 1.3% in 2000. - 1.3% in 2005 - 1.7% in 2010. - 1.8% in 2013. <u>Short-term</u> - 2.8% in 2000. - 3.1% in 2005 - 3.8% in 2010. - 3.9% in 2013.
<i>Wand B. M. et al. 2016</i>	To have experienced LBP for >3 months, scored ≥ 2 on a numeric rating scale, and ≥ 5 on the Roland Morris Disability Questionnaire	The whole sample had experienced LBP	Self-reported questionnaire about current pain medications	15.9% of the 251 people with CLB

<i>Vincent A. et al. 2015</i>	Patients with a diagnosis of fibromyalgia (HICDA or ICD-9)	The whole sample had Fibromyalgia	The use of medications documented in the medical record	22.4% among the 1,111 patients with fibromyalgia	
<i>Laroche, M R. et al. 2015</i>	Pain lasting at least 3 months	53% of the visits were for CP.	The primary outcome was prescription or continuation of an opioid medication during the visit.	Combining all years, opioids were prescribed to 20.8% (95%CI 18.9–22.6%) of CP visits. 12.9% (95%CI 9.7–16.0%) in 2001. 28.2% (95%CI 21.4–34.9%) in 2007. 23.1% (95%CI 18.3–27.9%) in 2010.	Patients aged 35–49 years vs. 50–64 years (OR=1.32 (95% CI 1.11–1.56)). Hispanic vs. non-Hispanic whites (OR=0.54 (95%CI 0.39–0.74)). Patients with Medicaid (OR= 1.46 (95%CI 1.16–1.85)), Medicare patients under age 65 years (OR=2.34 (95%CI 1.77–3.10)), and patients without insurance (OR=1.54 (95%CI 1.21–1.96)) vs. private insurance. Patients visiting their assigned primary care provider (OR= 1.39 (95%CI 1.15–1.68)) and patients previously seen in that office (OR=1.94 (95%CI 1.52–2.49)).
<i>Marschall, U. et al. 2015</i>	According to the International Classification of Diseases (ICD-10-GM)	The whole sample had CP.	The insurance organization long-term opioid therapy (LTOT) prescriptions: defined by at least one opioid prescription per quarter for at least three consecutive quarters (one quarter = 3 months) over the last 12-month. High-dose opioid therapy (defined by ≥ 100 mg MEQ/day)	<u>LTOT prescription all insureds with CNCP</u> 1.3% (range 1.2%; 1.4%). <u>High-dose opioid therapy among LTOT users</u> 15.5% (range 14.2%; 16.5%)	
<i>Kingsbury S. R et al. 2014</i>	Respondents who self-reported a	OA prevalence 6.5% - UK 10.9% - France 6.4%	Respondents were asked whether they currently use prescription to treat	16.7% - 19.3% in the UK - 27.7% in France	

	physician diagnosis of OA	- Germany 3.8% - Spain 6.3% - Italy 3.6%	their arthritis; if so, they were asked to indicate what they were currently using	-3.5% in Germany - 6.9% in Spain - 0.7% in Italy	
<i>Fredheim, O. M. S. et al. 2014</i>	Pain lasting 6 months or more and pain of at least moderate intensity during the last week before participation in HUNT 3.	31.6%	The National Norwegian prescription. Two different definitions of persistent opioid use included: - <u>The wide definition</u> clinically corresponds to using opioids most days of the week (>180 DDD or 4500 OMEQ) - <u>The strict definition</u> to using opioids around the clock all days (>730 DDD or 18,000 OMEQ). Data on dispensed opioid prescriptions during the 6 months immediately before participation in HUNT 3.	Opioid users among individuals with CP <u>Persistent opioid use</u> 2.9% <u>Occasional opioid use</u> 12.3%	- Being younger than 56 years old (OR=2.22, CI 95%: 1.65;2.99) - Male (OR=1.49, CI 95%: 2;1.11) - A current smoker (OR=2, CI 95%: 1.36;2.94) - Using more than 100 DDD of benzodiazepines per year (OR=5.55, CI 95%: 3.74;8.23) - Receiving prescriptions of drugs from several ATC classes (OR=4.98, CI 95%: 3.31;7.48)
<i>Azevedo L. F, et al. 2013</i>	Pain lasting at least 3 months	35.7% (95% CI, 34.38–37.02)	Respondents were asked if they were using any pain medicine. If so, they were asked for the drugs and the frequency	4.24% (95%CI: 3.31–5.41) among participants who responded if they were using any pain medicine (N=1786)	-Pain-related disability PDI (per increase in 10 units) OR=1.23 CI 95% 1.02–1.50)
<i>Henderson, J. V et al. 2013</i>	Pain experienced every day for three months in the six months prior to this consultation	18.8% (95% CI: 17.8–19.8)	Respondents were asked if their pain was being managed and how. If the answer was “with medication”, they were	32.7% among respondents with CP (N=1,088)	

			asked to specify which medication.	
<i>Häuser W. et al. 2012</i>	Fibromyalgia Syndrome (FMS)-diagnosis >1 month's duration	The whole sample had FMS	Participants were asked to "indicate whether they currently use any interventions for FMS". The interventions, including drugs, were listed in different sections.	<ul style="list-style-type: none"> - 17.6% Weak opioids - 8.4% Strong opioids

ABSTRACT

Objective. To investigate the evolution of opioid-related mortality and potential years of life lost in Spanish general population from 2008 to 2017. To evaluate the differences between Spain and US.

Methods: A descriptive study using retrospective annual data from 2008 to 2017 in Spanish and US general population. Information on the population and opioid-related deaths stratified by age and sex was obtained from Spanish National Statistics Institute and the Centers for Disease Control and Prevention (CDC) WONDER Multiple Cause of Death Database, according to the ICD-10 codes. Years of life lost, crude and standardised mortality rates are reported and compared with the results in US.

Results: Crude rate of opioid-related deaths per 10⁵ inhabitants has changed from 1.68 in 2008 to 2.25 in 2017 in Spain, with around 30 000 years of life lost per year. The most affected groups were middle-aged men and women over 65, and the main cause of death was accidental poisoning. The standardised rates per 10⁵ inhabitants across the years were between 1.19 and 1.62 in Spain and between 11.17 and 20.68 in US population.

Conclusions: An opioid overuse crisis does not seem a likely scenario in Spain. However, it is a social problem that requires special health surveillance, particularly in middle-aged men and women over 65.

Keywords: Opioid; Mortality; Years of life lost; Spanish population; US population.

INTRODUCTION

The prescription and consumption of opioids has changed in many countries in recent years as it is becoming a serious health problem in some cases [1–6]. According to the World Drug Report 2017 [7], 29.5 million people globally suffer from drug use disorders, being opioids the most harmful. The United Nations has warned of an opioid overuse crisis in the USA in 2017, although this is not the only country in which its consumption has increased [1]. In Europe, Bosetti et al [2] reported an increase in opioids consumption, with relevant differences between countries. Particularly, these authors observed the highest consumption in Western/Northern European countries and the lowest consumption in Southern/Eastern countries. Some authors [2,3] identified an upward trend similar to the USA. Although in the country where the consumption is the highest in Europe (Germany), it is approximately half of the level in the United States [3]. Despite this, a crisis similar to the US is anticipated in other countries such as the United Kingdom in 5 or 10 years [4].

In Spain, data reported by Garcia del Pozo et al in 2008 [5] revealed a huge increase in opioids consumption at the end of the 20th century and the beginning of the 21st century. More recently, The Spanish Agency for Medicines and Health Products quantified the increase from 7.25 Defined Daily Dose (DDD) per 1000 inhabitants per day in 2008 to 13.31 in 2015 [6], which represents an increase of 83.59%. However, it is not clear if the situation has worsened in recent years, and there is currently a debate in the scientific community about whether Spain presents a similar trend to the United States, and if we are on the way to a possible overuse crisis.

The aforementioned crisis is not something to be taken lightly, as higher doses of medically prescribed opioids may lead to opioid overdose [8]. This finding challenges the traditional idea that opioid overdose is related to non-medical users [9]. In addition to overdoses, many of the problems associated with the use of opioids, such as addiction, abuse or dependence [4,9–13], greater physical and psychological comorbidities [8,14–18], an increase in opioid-related mortality and potential years of life lost [4,19], have been reported. Some authors even report that the risks of opioids outweigh the benefits [4,20], and the opioid abuse can have clinical and economic consequences in the society, including patients, health care professionals, and the government [14].

Meyer et al [14] has estimated a cost of \$55.7 billion attributable to prescription opioid abuse in 2007 as well as an increase of 124% in the rate of unintentional overdose deaths. This increase has been observed by other authors, particularly in the USA and Canada [19,21], being a problem

that affects especially people aged 25 to 44 [21]. This fact aggravates the situation in terms of early loss of life. Few studies have reported the data on years of life lost (YLL), either globally [22] or in the United States specifically [10,19], where it has been estimated at 830 652 YLL among people younger than 65 years in 2008. However, to the best of our knowledge, there are no studies in Spain analysing this, even though YLL is an indicator of great importance in this context, as it quantifies the costs of opioid-related deaths (ORD).

As the situation in the USA has been described as alarming, and there is evidence that some countries could be on the same path, it is important to know the situation in a country like Spain, where an increase in opioid consumption has been observed, and a similar tendency might be plausible. Replicating in Spain the results obtained by Gomes et al [19] in the US would allow us to compare the situation and can prevent a possible overuse problem.

In view of the above, we aimed to investigate the evolution of opioid-related mortality and potential years of life lost in Spanish general population from 2008 to 2017 and to compare it by gender and age. We also aimed to know the differences between Spain and the USA.

METHODS

This is a descriptive study using the retrospective annual data from 2008 to 2017 in the Spanish general population. It is based on the methodology previously used by Gomes et al [19] in the USA to compare populations.

Information on the population and ORD stratified by age and sex was obtained from the Centers for Disease Control and Prevention (CDC) WONDER Multiple Cause of Death Database for the USA [23], and the Spanish National Statistics Institute (INE, for its acronym in Spanish) for Spain [24].

The INE carries out the "Statistics of deaths according to the cause of death" [25] following the criteria established by the WHO in the International Classification of Diseases (ICD-10) [26], which includes more than 12 000 diseases. This statistic provides information on mortality according to the basic cause of death and its distribution by sex and age, among other factors. A similar methodology is used by the CDC.

From these data, and according to the ICD-10 codes [26], we retrieved information on ORD specifically due to accidental poisoning (X40-X44), intentional self-inflicted poisoning (X60-X64), aggression (X85), and poisoning of not determined intention (Y10-Y14).

For each year (from 2008 to 2017), we report stratified (by sex and age) data on number of ORD, crude and standardised rates of ORD per 10^5 inhabitants, years of life lost (YLL), YLL per 10^4 inhabitants, number of deaths by type of opioid-related death. Crude rate of ORD is defined as the quotient between the number of ORD and the total population, expressed in terms of number of deaths per 10^5 inhabitants. YLL are defined as the sum of the remaining years that a person who has prematurely died due to opioids has not lived, that is, the sum of the difference of life expectancy and the age of death of each person who has prematurely died due to opioids. Type of opioid-related death is a qualitative variable classifying the deaths in accidental poisoning, intentional self-inflicted poisoning, aggression, and poisoning of not determined intention. The data presented are tabulated in absolute terms and crude rates. We report the number of deaths by type of death and year in Spain, for the total population, men and women separately, in bar plots.

The evolution over time of the standardised rates of ORD in total population, men and women, is presented in a line chart for both Spain and the USA. For this comparison, we standardised the data taking into account the different distribution of the two populations by ages. For this standardisation, the direct method was used: the rate of each stratum in each population was applied to the world standard population provided by the WHO [27] to obtain data on the expected deaths, which were subsequently added and divided by the total standard population to obtain the standardised rates per 10^5 inhabitants. We report these standardised rates in a line chart.

All the analyses and figures were performed using the software Excel 2016.

RESULTS

Opioid-related deaths and years of life lost in Spain due to opioids in the period 2008-2017.

Between 2008 and 2017, a total of 8506 people died due to opioids, including accidental poisoning, intentional self-inflicted poisoning, aggression, and poisoning of not determined intention (Tables 1A and 1B). The cost, in terms of YLL, was 290 093.33 years (Tables 2A and 2B).

The crude rate of ORD per 10^5 inhabitants in the whole population has fluctuated (around 2) over the years (from 1.68 in 2008 to 2.25 in 2017), showing a slight upward trend in men from 2011 to 2017, and in women in the whole period. Crude rates in men are always above crude rates in women (around 1 point above) (Tables 1A and 1B).

The most affected age groups were, in almost all the cases, 35-44 and 45-54, but it is remarkable the increase of the crude rates in the group of 65 or more years (from 1.25 in 2008 to 3.8 in 2017). In this regard, we observed differences between men and women, with men most affected in the age group 35-54, and women in the age group over 65 (Tables 1A and 1B).

Regarding the YLL, we further observed a fluctuant situation, with a minimum of 24 497.35 YLL in 2011 and a maximum of 32 648.99 in 2016 in the whole population (Tables 2A and 2B). Nevertheless, it was different between men and women. In particular, men lost more years of life, even more than twice than the women in most cases. The largest amounts of YLL were observed in the age group 35-44 (Tables 2A and 2B).

Number of deaths by the type of opioid-related death and year.

Most of the deaths had a well-defined cause, with only a few cases due to poisoning of not determined intention (Y10-Y14). In addition, as the years went by, the number of indeterminate cases decreased. Aggression (X85) was the least frequent cause of all (Figures 1A and 1B).

In the total population, the main cause was accidental poisoning, followed by intentional self-inflicted poisoning. When analysing by sex, the number of deaths due to intentional self-inflicted poisoning was similar in men and women, but a substantial difference in accidental poisoning was evident. Specifically, the number of deaths was higher in men compared with women (Figures 1A and 1B).

Comparison of opioid-related mortality between US and Spanish population.

After the standardisation of the rates, we observed a better situation in Spain than the USA (Figure 2). In the total population, the standardised rates per 10⁵ inhabitants across the years were between 1.19 and 1.62 in Spain and between 11.17 and 20.68 in US population. This difference was even more evident for men, and slightly lower (but still relevant) for women. A greater increase in US standardised rates in recent years was observed, compared to the slight increase in Spain after standardisation. (Figure 2).

DISCUSSION

In this study, we have analysed the ORD in terms of the evolution of opioid-related mortality and potential years of life lost in Spain in the previous years. We have performed a comparison between Spain and the USA. Generally, our results reflect a better situation in Spain than in the

USA, although we cannot ignore the upward trend in the opioid-related mortality and the years of life lost.

Specifically, we found between 691 and 1049 deaths per year. Given the data on the considerable increase in the prescription and consumption of opioids previously reported [5,6], a greater increase in associated mortality could be expected; however, the increase is not a significant reason for concern.

The worst evolution has been observed in men in the study of Gomes et al [19], and this pattern is repeated in the rest of the results. Gomes et al also point out that the burden of ORD is higher among men, and our results confirm that in Spain as well. The number of YLL is worrisome in the whole population, but especially in men. According to the Spanish Report on alcohol, tobacco and illegal drugs 2017 [28], the main psychoactive substances responsible for deaths in recent years are hypnotosedatives and opioids, followed by cocaine and alcohol, the latter in a lesser proportion. In more than half of the deaths in which toxicological information was collected, opioids were involved. However, the report does not specify if it was the main cause of death. In any case, this means that we must pay special attention to the consumption of opioids, as these are involved in many deaths, and our data identify these as the main cause of death. Historically, addiction to opioids has always been higher in men. In addition, it has been shown that men are more likely to increase the dose of opioid therapy compared with women [29], which is in line with our results. However, recently, there is more controversy in this regard, with higher levels of addiction in women in some cases [30–33].

Regarding the differences by age, we observed that the most affected ages were 35–54, similar to the US population [19]. However, in the group over 55 in the USA, an increase in the rates has been observed. This was also observed in our data in Spain in some of the studied years, mostly in women. It could be argued that this is due to the greater use of these drugs in cases of terminal diseases, although it must be taken into account that the registered main cause of these deaths is not the disease, but the opioid. Besides, this would not explain the gender differences. The prevalence of chronic pain is higher in women of this age group [34], with opioids being one of the most used treatments for pain [35]. A systematic review published on sex differences in opioid effect on pain [36] has found that side effects such as emesis and respiratory depression, the latter often related to an eventual death [37], are more pronounced in women. However, there is limited information on gender differences in opioid use risk factors, and a more in-depth study is required to identify whether this could explain the observed differences in mortality in women of this age group.

The main cause of death was accidental poisoning, not intentional poisoning. Roxburgh et al [38] have reported that the increase in opioid deaths was mainly caused by accidental overdoses in the Australian population, and some authors also found an increased risk of accidental death in the case of co-prescription [37]. A previous study found that even the single prescription of opioids is associated with the risk of future ORD [29]. Therefore, it is important to emphasise education and rationalise the use of these drugs to prevent accidents, as suggested by other authors [37,38], especially in men whose death rates are higher compared with women in Spain.

The comparison of the standardised rates of opioid-related mortality between Spain and the USA is significant. Even after standardisation, the ratios are clearly different between the countries, 8 to 12 times higher in the USA compared with Spain, depending on the year (the more recent, the greater the difference), and this difference is more pronounced in men, in accordance with the results by Gomes et al [19]. In this regard, Bosetti et al have reported that the Southern and Eastern European countries (Spain included) have the lowest consumption [2], which would imply, a priori, a lower risk. Additionally, a recent study of Chen et al shows that, in Europe, the most concerning increases in drug overdose deaths from opioids have been observed in the northern countries such as Estonia, largely caused by fentanyl [39]. The previous considerations indicate that, despite the increase in mortality, the situation in Spain is far different from the situation in the United States or some other countries [2–4].

Finally, we have to point out some limitations of this study. The use of secondary data is always a potential limitation, although the data were collected exactly as we needed for the purpose of the study, with precise definitions using ICD-10 codes. In addition, the data were obtained from reliable sources. However, the reliability of the determination and coding of the cause of death depends on each professional in each of the deaths, and not on the data source itself. Because of this, we believe that there is a possibility of underestimating the number of ORD, as in some cases this information may be omitted to avoid legal or administrative issues, especially in the case of accidents. Among the strengths of our study, we highlight the comparison between countries, as it provides information whether the situation in Spain is similar to the situation in the USA. Finally, the importance of the subject addressed here is another strength of the study.

CONCLUSION

The crude rate of ORD per 10⁵ inhabitants has changed from 1.68 in 2008 to 2.25 in 2017 in Spain, with around 30 000 years of life lost per year, being middle-aged men and women over 65 the most affected groups. The standardised rates in US population are 8 to 12 times higher

compared to standardised rates in Spain. An opioid overuse crisis does not seem a likely scenario in Spain. However, it is a social problem that requires special health surveillance, particularly in middle-aged men and women over 65.

ABSTRACT

Context: A lack of information has been found related to patients' perception towards pain management.

Objectives: To analyze the point of view of the general Spanish population regarding the use of opioids in pain treatment. To identify groups of individuals based on this information.

Methods: Nationwide cross-sectional study on a representative sample of 1,299 Spanish adults. Data were collected on beliefs, knowledge, fears, opinions and, attitudes towards the use of opioids. A cluster analysis to identify groups of people based on these parameters, and a multinomial logistic regression model to analyze the variables related to the clusters were performed.

Results: Three groups of subjects were identified based on their perspective towards opioids: A group with a positive point of view (N=448) composed of people >65 years who would accept a treatment if prescribed and who were less fearful of these drugs; A group with a moderate point of view (N=337) formed by younger subjects with university education, better informed about opioids, afraid of these drugs (OR=2.67), and more frequently associated them with drowsiness (OR=2.58), nausea (OR=3.04), and tolerance (OR=2.16); A third group with negative point of view (N=468), with lower educational level who would more often reject treatment with opioids, more afraid of them (OR=3.95), considering that they may not be able to stop the treatment (OR=3.04) and may produce tolerance (OR=3.03).

Conclusions: The different perspectives of patients regarding the use of opioids to treat pain should be taken into consideration by the physician when designing strategies to inform patients about the treatment of pain with opioids. This should promote their correct use, specially preventing their misuse.

Keywords: Opioids, Beliefs, Knowledge, Attitudes, Opiophobia and Epidemiology.

Running Title: Vision towards the use of opioids in Spain.

INTRODUCTION

Opioids are drugs that are widely used in pain treatment worldwide, and that the World Health Organization (WHO) considers essential for the control of moderate and intense pain, particularly of oncological origin (1). For some years now, awareness has been on the rise regarding the treatment of pain in Spain because of the progressive increase in the number of pain units in hospitals and of the enhanced emphasis on pain management in the palliative care. Likewise, the prescription and use of opioids increased between 2008 and 2015 in Spain (2) but without reaching the levels observed in other European countries like Denmark (3).

Several studies have shown that some patients consider that the medical prescription of opioids is sometimes associated with terminal illness and imminent death (4). Likewise, these drugs have also been related to negative side effects, such as excessive sedation, respiratory failure, urinary retention or constipation, among others (5). This situation along with social, cultural and historical factors (6) have led to what is known as "opiophobia", a set of inappropriate attitudes and beliefs regarding the deleterious effects of opioids administration for pain relief (7). This has been related to reduced prescription of these drugs by health professionals and lower consumption by patients (8).

By contrast, in other countries where the prescription of opioids has risen considerably in recent years, it has been reported that between 24.0% and 37.1% of the patients with chronic pain may often misuse of these drugs (defined as the use of any addictive drug in a manner other than how it is indicated or prescribed) (9), which has raised some alarm among this population (10). This situation has led to the need to identify patients at risk, and to monitor their behavior more closely (11).

In view of the differences observed in studies into the viewpoints of patients regarding the use of opioids to treat pain, we conducted a population-based survey to determine the current beliefs, opinions, and attitudes of the Spanish population towards opioid use in the treatment of pain. We set out to identify groups of individuals based on their point of view regarding these drugs and to analyze the factors that influence this perspective in each of the groups identified.

METHODS

This cross-sectional study was carried out on a representative sample of the general adult population in Spain, obtained using a multistage, stratified sampling method. The eligible

population consisted of individuals aged ≥ 18 years who resided in households with a landline telephone, who agreed to participate in the study and who were able to complete the questionnaire. The exclusion criteria were individuals younger than 18 years of age, lack of a landline telephone at home, or the inability to respond to the questionnaire.

Sampling Method

The Spanish territory was divided into 8 strata or areas based on geographical and historical boundaries. For each stratum, 20 municipalities were randomly selected, taking into account the Spanish rural/urban ratio of 25:75, and considering municipalities with $<10,000$ inhabitants as rural and those with $>10,000$ inhabitants as urban areas.

The total number of subjects required for the study (see below) was distributed in proportion to the size of each municipality. In addition, the number of subjects was divided into 6 strata, according to the sex and age distribution of the population (18 to 44, 45 to 64 and 65 or over). The selected individuals were contacted through their landline telephone using the Infobel España Office v.7.1 digital telephone directory. This directory includes the telephone numbers of 90% of all Spanish households with a landline telephone and considering that 80.6% of Spanish households have a landline telephone, we had access to 72.5% of the eligible Spanish population.

Sample Size

The sample size was determined based on the study of Schiller et al.(4), in which it was estimated that 50% of subjects were afraid of taking morphine. Setting a significance level of 95% and a precision level of 5%, the required sample size was established as 1,155 subjects. In order to guarantee the number of subjects calculated and considering the response rate in a previous study involving a telephone survey (12), the amount of telephone numbers randomly selected was three times that of the required sample size.

Procedure and instruments

Data were collected via a computer assisted telephone interview (CATI) using the Skype and the SurveyMonkey platforms, whereby the interviewers recorded the data while the interview was being conducted. The interviewers received training on the purpose of the study, the working protocol and on the use of the SurveyMonkey platform. In addition, data collection was coordinated and supervised on a daily basis by a member of the research team, addressing any

problems that had arisen. Before the interview, all subjects included in the study gave their informed consent, and the study was conducted in accordance with the Helsinki Declaration, using Standard Working Procedures and Protocols.

Survey structure and topic

The survey was structured in 6 blocks of questions: the *first block* was designed to *obtain* personal information; the second block was related to the respondents' beliefs about opioids, and in this case the information was collected from an open-ended question in which the interviewees were asked what was the first thing that came to mind when they heard the word "opioid"; the third block revealed the level of the respondent's contact with opioids and their knowledge of them; the fourth block explored the fears (side effects, death, becoming an addict, not achieving the desired results, and death) related to the opioids intake; the fifth block collected the opinions of the responder regarding this type of treatment (tolerance, dependence, severity of the disease); and the sixth block addressed the responders' attitude towards these drugs. This attitude was obtained by means of a question that asked whether the respondent would agree to treatment with this medication or not if their doctor prescribed it. The questions that set out to collect information about beliefs, fears and opinions were assessed using a 5-point Likert scale ("not at all", "a little", "some", "quite a lot" and "a lot").

In order to facilitate the analysis and interpretation of the results, three new variables were created. The first variable was designated as the "level of contact with the treatment" and it was constructed using three questions that referred to the drugs Tramadol, Morphine, Tapentadol, Oxycodone, Fentanyl and Buprenorphine. The questions were:

1. *"Are you currently following a treatment with any of these opioids?"* If the answer was affirmative, we considered the respondent to have "maximal contact" with opioids.
2. *"Have you ever been treated with any of these opioids?"* If the answer was affirmative, we considered the respondent to have "medium contact" with opioids.
3. *"Do you know anyone who is currently or has ever been treated with an opioid?"* If the answer was affirmative, we considered the respondent to have "minimal contact", while they were considered as having "no contact" if the response was negative.

A second variable, considered "level of opiophobia", was established based on four questions gathering information about the individual's fear of: side effects, becoming an addict, not achieving the desired results, and death. The responses to these questions were categorized on a scale ranging from 0 = "not at all" to 4 = "a lot". The final score of this new variable was the

sum of the scores given on a scale from 0 to 16, where 0 is equivalent to no opiophobia and 16 corresponded to maximal opiophobia.

In addition, to determine the respondents' knowledge about the opioids indicated above, a third variable was created that we called "correct identification of opioids" based on the responses to the questions: *"Have you heard of any of the following medications?"*; and *"Could you tell me which of the following drugs you think is an opioid?"*. The answers to these questions were dichotomous ("Yes" and "No") and we considered that an individual correctly identified the drugs only if they responded affirmatively to both questions.

Statistical Analysis

A descriptive analysis of the variables studied was carried out, calculating the frequency, central tendency and dispersion. In addition, a hierarchical cluster analysis was performed to establish groups of individuals or patterns according to the subjects' opinions, fears, knowledge, level of contact and attitude toward opioids. The Euclidean distance between the groups and cluster formation criteria were used. Subsequently, the differences between the groups were analyzed using Chi-squared tests. In addition, a multinomial logistic regression model was established to determine the factors associated with each of the groups previously identified in the cluster analysis. The covariates included in this model were the significant variables identified in the bivariate analysis.

RESULTS

General characteristics of respondents

We carried out 3,844 contacts, 1,299 of which considered valid. The response rate was 33.79%. Of the total number of subjects interviewed, 50.7% were women and the global average age of the cohort was 50.48 years (SD=15.9). The majority of subjects had completed secondary education (45.9%).

Morphine was the best-known medication (99.2%) and it was correctly identified by 64.9% of respondents. However, fewer subjects correctly identified Tramadol (14.2%), and while oxycodone was recognized by 11.3% of respondents, Fentanyl, Buprenorphine or Tapentadol were only identified correctly by slightly more than 5% of them. More than 50% of participants knew someone who had taken opioid medication (minimal contact with treatment), although only 3.8% were taking any of these drugs at the time of the interview (maximum contact) (table

1). Most of the subjects with maximum contact were women (60%), over 65 years and mainly with primary education (43%).

Beliefs, fears, opinions and attitude towards opioids

Figure 1 is a Word cloud showing the beliefs of the respondents with regard to opioids, where the size of each word indicates how often the respondents related it to opioids. Although the most frequent response was "I do not know with which word to relate them", the words "pain", "illegal drugs", "medications", "opium" and "painkillers" were much repeated (figure 1).

Regarding fear of opioids (figure 2), side effects (48%) or of a failure to achieve the expected results (47%) were the fears most frequently reported by respondents, although nearly 35% of them expressed the fear of becoming addicted.

With regard the respondents' opinions on opioids, most of the interviewed agreed that these drugs may cause sleep or sedation (50.8%), that they are used when a disease is severe (42.6%), and that increasingly large doses are required (44.7%). However, almost 50% of them disagreed that opioids should only be used with terminally ill patients. Only slightly more than 30% of the respondents related these drugs with constipation (table 2).

When analyzing the attitude of the respondents towards the use of opioids, it was notable that most of respondents stated that they would agree to take them if they were prescribed medically (86.3%) as they generally placed confidence in their doctor (64.4%).

Patterns of opinions, fears and attitudes in the population surveyed, and associated factors.

From the clusters analysis, three groups of subjects were identified (table 3).

The first group (N=448), considered with the most Positive Point of View (PPV) towards opioids, was mainly composed of individuals over 65 years who would accept opioid treatment if it were prescribed by a doctor. In addition, they reported fewer fears towards these drugs, and they were more frequently of the opinion that opioids do not cause side effects and they are not associated with terminal illness, addiction or the need to increase the dose in order to achieve the desired effect (tolerance).

The second group (N=337) was characterized by having a Moderate Point of View (MPV) toward opioids and it was comprised of a larger proportion of young people with university education. The individuals in this group more often identified the opioids correctly than those in the other

2 groups and they not only thought that these drugs produced side effects (sleep, nausea, constipation), but they were also afraid of not getting the expected results if they took them. The third group (N=468), with the most Negative Point of View (NPV) towards opioids, included the subjects with the lowest educational level and with a stronger negative attitude regarding the acceptance of treatment with these drugs. These individuals had the highest level of opiophobia and they had the worse opinion of these drugs, considering them associated with terminal illness, addiction and tolerance.

Factors associated to each group identified according to their point of view toward opioids

The opinion that increasingly large doses of opioids are required (MPV:OR=2.16; NPV:OR=3.03) and a higher level of opiophobia (MPV:OR=2.67; NPV:OR=3.95) were the two variables most strongly associated to the groups with a worse vision of these drugs (MPV, NPV versus PPV). However, while respondents in the MPV group more strongly agreed that opioids produce sleepiness (OR=2.58) and nausea (OR=3.04), respondents with a more negative vision (NPV) placed more importance on not being able to stop taking them whenever they wanted to (OR=3.04) (table 4).

DISCUSSION

To our knowledge, this is the first study carried out in Spain to analyze the perspective of the general population toward opioids, based on the beliefs, knowledge, fears and opinions. This analysis enabled us to identify three groups of individuals with a clearly distinct point of view regarding these drugs, as well as specific factors associated with each of these groups.

Among the results obtained, it is noteworthy that most respondents did not have a clear idea about opioids and those who did, mostly considered them to be related with "pain", "illegal drugs" and "medication". This is consistent with the findings of a study carried out in Portugal (13) where 32.3% of the general population were unable to recognize the term "morphine". However, when these individuals were specifically asked about this drug, 99.2% answered that they knew about it even though it was only identified as an opioid by 64.9% of them.

In our study, 3.8% of the respondents were under a treatment with opioids at the time of the survey. This is similar to the situation described in Portugal (4.37%) (14), and in Scotland, where the opioid use increased to 3.6%, mainly due to the use of Tramadol(15). According to the report of the Spanish Agency of Medicines and Sanitary Products (2), Tramadol is the opiate that has

experienced a greater increase in use in recent years, which may explain why it is the best known opioid after morphine in our study.

It is important to note that three different profiles of participants were identified in this study, including a group of better-informed young people who are more concerned about the side effects of opioids, who have a more critical attitude towards opioids and who are less willing to take them upon medical prescription (MPV). Another group of participants with a generally lower educational level (NPV) seemed to show more deep-rooted opiophobia. Finally, there was a group of older respondents who had more confidence in their physician when prescribed these drugs and they were less concerned about their adverse effects (PPV). In this vein, it is noticeable that, as other studies show, elderly patients assume pain and taking medication as part of their aging process and only 15% expect that the treatment has few side effects (16). This could explain the results found in our study regarding older people being less afraid of the adverse effects associated with opioids.

Similarly, the higher educational level of the youngest group in our study could condition their attitudes, making them more demanding with the treatment. The WHO states that, among other educational organizations, universities play a key role in establishing knowledge, behavior and attitudes towards health, promoting the "empowerment of students in health" and enabling them to better control adverse health determinants (17). This could explain why the youngest group with the highest proportion of individuals with university education is indeed more critical, not only of the most well-known aspects of these drugs like addiction and tolerance, but also, of other less common aspects that may affect their quality of life.

Studies have shown that when taking opioids, confidence in their effects and a positive attitude towards them is closely related to the improvement in the quality of life and the pain relief obtained by the patient, or that described by acquaintances and relatives (18,19). This circumstance could explain the results observed in the PPV group, which was precisely the group with the greatest level of contact with these drugs. An alternative explanation could be that a greater exposure to opioids expels the fear of their adverse effects, tipping the balance in favor of their pain-relieving effects. This hypothesis could be particularly relevant if we consider that this group included an older population that might be more concerned about pain relief and less concerned about the side effects of these drugs (18,19).

Tolerance was identified as a risk in both the MPV and NPV groups. The NPV group referred to the risk of being unable to stop taking opioids, these individuals were more reluctant to accept

them if prescribed by a doctor. One of the reasons for maintaining inappropriate beliefs and attitudes towards these drugs may be a lack of knowledge about them, leading to opiophobia, a phenomenon that includes a fear of tolerance (7). This is consistent with the characteristics of the NPV group, where the respondents attained a generally poorer level of education.

In accordance with our results, fear of addiction has previously been shown to be an important barrier to opioid use in patients suffering moderate or severe chronic pain, representing one of the reasons why this pain is often under treated (20,21). Indeed, opioid use in the United States represents 80% of the total worldwide consumption (22,23) and the misuse behavior rate is 34.1% (24), much higher than in other countries. Given the importance of controlling pain in patients with chronic moderate or severe pain and avoiding problems of the misuse of opioids, it is important to find a balance between these two extremes in the Spanish population. Thus, identifying groups with different perceptions towards opioids, such as those observed in the present study, should be useful when establishing future healthcare strategies.

Finally, some strengths and weaknesses of the present study should be noted. One strength is the clusters analysis used to identify different groups of subjects based on beliefs, fears, opinions and attitudes towards opioids, stands out as one of the strengths of this work. Other studies (12,25) have applied this analysis to cohorts of patients with chronic pain, demonstrating its usefulness. However, as far as we know, this is the first time that this type of analysis has been applied in this kind of study. Another strength is that the study was carried out on a large sample from the general population using an exhaustive sampling procedure, representing populations of different ages and sex.

Among the weaknesses of the study, we must consider that the information was gathered by telephone, which limited the duration of the interview. However, the use of telephone surveys has been considered by some to be more adequate in population studies than "face-to-face" surveys (26), particularly since they allow greater coverage of the *population* being *studied* and they permit a representative sample to be obtained by randomization of telephone numbers. Another issue that must be taken into account is the low response rate observed in this study (33.79%), which could have introduced selection bias. However, we consider that this is unlikely to affect the validity of the results since the distribution of the sample is identical to that of the target population, ensuring that the responses are representative. Furthermore, although higher response rates have been obtained (e.g., 70%) (21), rates similar to ours (33% and 42%) were also reported using the same method (27,28).

Another possible limitation is that we did not assess “opiophobia” directly and its measurement was based on four questions about the individual’s fear (side effects, becoming addicted, not achieving the desired results, and death). However, the term “opiophobia”, as previously described in the introduction(7), is a definition that includes similar issues as those considered in this paper. Given that the general population was target in this study, we believe that the inclusion of the exact definitions of both tolerance and dependence in the questionnaire would have complicated the collection data.

In summary, as well as demonstrating the lack of knowledge in the Spanish population about opioids, this study shows that the side effects of these drugs are the most feared aspects associated with their use in the treatment of pain. Furthermore, this study reveals the factors related with the different perceptions and concerns among the general population regarding the use of opioid treatments, which largely depends on educational level, age and prior contact with opioids. Healthcare professionals should pay particular attention to the patient profile when designing strategies to inform patients and treat their pain using opioids. The information given should be personalized to suit the patient’s characteristics, paying special attention to the possible benefits of the treatment in the MPV and NPV groups, and to the risks and adverse effects in the group with PPV. This should improve the clinical management of opioids and promote their correct use, specially preventing their misuse.

Disclosures and Acknowledgments

This work was supported by the External Chair of Pain, a collaboration between the University of Cádiz and the Grünenthal Foundation. The Grünenthal Foundation is a private non-profit making organization that promotes the dissemination of scientific knowledge and supports research. The authors would like to acknowledge the effort of the interviewers who collected the data through the telephone interviews.

* The author of this thesis contributed to this work by performing the fieldwork, analysing the data, and was mainly responsible for writing the manuscript.

ABSTRACT

Background: opioids are one of the most prescribed treatments for chronic pain (CP). However, their long-term use (>3 months) has been surrounded by controversy, due to loss of beneficial effects.

Objective: to explore the experiences of people with chronic non-malignant low back pain in Spain undergoing long-term treatment with opioids.

Design: qualitative study

Setting and participants: we conducted 15 semi-structured interviews at the Pain Clinic with persons taking opioids treatment.

Methods: The interviews were analyzed by qualitative content analysis as described by Graneheim and Lundman, and developed categories and themes discussed in light of a biomedicalization framework.

Main results: we developed one overarching theme - *Living with opioids: dependence and autonomy while seeking relief* - and three categories: *The long pathway to opioids due to the invisibility of pain*; *Opioids: from blind date to a long-term relationship*; and *What opioids cannot fix*.

Discussion: The long and difficult road to find effective treatments was a fundamental part of coping with pain, involving long-term relationships with the health system. This study reflects the benefits, and drawbacks of opioids, along with struggles to maintain autonomy and make decisions while undergoing long-term treatment with opioids. The paper also highlights the consequences of pain in the economy, family and social life of patients.

Conclusions: patients' experiences should be considered to a greater extent by healthcare professionals when giving information about opioids and setting treatment goals. Greater consideration of the social determinants of health that affect CP experiences might lead to more effective solutions to CP.

Chronic Pain; Low Back Pain; Opioid; Treatment; Biomedicalization; Experience

INTRODUCTION

Chronic pain (CP), defined as pain that persists beyond the normal tissue healing time (3 months as a convenient cut-off point), is a health problem that has reached epidemic proportions worldwide. The average CP prevalence is 27% in European countries, consistent with international estimates ¹. In Spain, around 17% of the population suffer from this illness, making it a major healthcare problem ².

Opioids are one of the most prescribed analgesic pharmacological treatments for CP ³. Prescriptions for opioids have increased dramatically in the last few decades, numbers being far higher in countries such as the United States or Canada ⁴. According to the National American Survey on Drug Use and Health (NSDUH) report in 2016, more than one-third of American adults were prescribed opioids⁵. Although to a lesser extent, an increase has also been observed in some European countries^{6–8}, including Spain (83.59% from 2008 to 2015) ⁹.

Opioid therapy has been found to be associated with the alleviation of pain in the short term ¹⁰. However, their prescription for long-term use sometimes presents a dilemma ¹¹, since it has been accompanied by a great increase in overdoses, abuse, addiction, and recreational use in some countries such as the United States ¹². Clinicians therefore face the potentially conflicting duties of relieving pain on the one hand, viewed worldwide as an ethical medical obligation ¹³, and preventing the potential harm to the patient of long-term opioid consumption on the other ¹⁴. Dispelling the myriad myths associated with pain and fears associated with opioid prescription is no easy matter. Part of the solution depends on educating and training health care professionals in pain management ¹⁵.

Patients who experience CP could also face this quandary since opioids have been related to negative side effects, such as excessive sedation, respiratory failure, urinary retention, or constipation ¹⁶. These side effects, along with social, cultural, and historical factors, have given rise to a set of attitudes and beliefs regarding the deleterious effects of opioid administration for pain relief ¹⁷. The main reasons for this inappropriate set of attitudes and beliefs are the lack of knowledge regarding opioids and the stigmatization that some patients felt when prescribed opioids ¹⁸.

The benefits of opioids have also been surrounded by controversy ¹⁹. Some studies ^{20,21} have shown that most people using opioids continue to report moderate or severe pain, and that functional improvements are often limited. Other authors ²² have shown that increases in the intensity of pain are connected with skipping doses, since patients reduce or stop taking their

opioid therapy to avoid side effects. Despite the existence of clinical guidelines that regulate the correct use of opioids in the treatment of pain ^{23,24}, in Spain, CP management still remains weak ²⁵. Fear of addiction might be an important reason why CP is often undertreated ¹⁶.

Recent literature ^{18,26–28} has explored the experience of adults using prescription opioids to manage CNCP, concluding that there were many negative aspects to using opioids daily, in most cases these were outweighed by the positive effects and most of the negative aspects were socio-culturally induced rather than caused by the drug itself. However, these studies have been carried out in countries such as the United States or Canada, where the trend of opioid use has been accompanied by an increase in reported opioid abuse and opioid-related death ²⁹ which is a different situation compared to Spain ^{30–33}.

Considering the potential worries and difficulties associated with the use of opioids, it is very important that patients communicate and relate to healthcare providers their experience with opioids in an open and effective manner. However, although the number of individuals living with CP and taking opioids is increasing, to the best of our knowledge, no study has been performed to explore the experiences of patients taking opioid medications in Spain. Thus, this study aims to fill this gap in knowledge by exploring the experiences of patients with CP receiving long-term treatment (more than three months) with opioids in Spain.

Spanish healthcare system

The Spanish healthcare system has universal coverage, is almost entirely funded by taxes and is free of charge at the point of delivery, except for pharmaceutical products for people under 65, which require a co-payment of 40% of their price. Provision of care is predominantly within the public network of healthcare facilities. Primary healthcare is the first point of contact for individuals with the healthcare system, and thus professionals working there as GPs, nurses and midwives act as gatekeepers of the system. The primary healthcare network is an integrated part of the public systems through mutually supportive referral systems with secondary and tertiary healthcare facilities. In the case of patients who experience CP, after visiting their GP they are referred to a specialist, usually a rheumatologist or traumatologist, and then to the Pain Clinic if the pain does not remit.

The Pain Clinic is a unit specialized in the management and treatment of all complex types of pain conditions, especially in those patients who do not respond to conventional treatment and those who require special drugs or treatment techniques, such as local infiltration of anesthetics and/or steroids or radiofrequency neurolysis.

Opioid treatments can be prescribed by GPs or specialist doctors. All official opioid prescriptions must include the denomination "Official Narcotics Prescription", with the exception of those that are issued in electronic format. In each Official Narcotics Prescription only one type of opioid treatment must be prescribed, with a maximum treatment length of three months and without exceeding a total of four containers.

Theoretical Framework

CP is considered to be a complex biopsychosocial event ³⁴. Besides the physical experience of pain, individuals suffering from CP often experience mental and emotional disturbances and their family environment might also be severely affected ³⁵. Given its complexity, healthcare services should address CP following a multidisciplinary approach, although pharmacological therapy is still considered the cornerstone (and sometimes the only approach) of the control of pain ³⁶. Moreover, as we have previously described, long-term treatment with opioids might help to relieve pain in some cases, but result in other issues related not only with adverse effects, but also with communication, negotiation and power relationship problems between patients and providers, stigma and the role of family and support networks. Following an emergent design, a biomedicalization framework was chosen, meaning that the analysis of the interviews guided the choice of theory. Thus, the theoretical framework was mainly used in the discussion section to contrast the results of this study with previous evidence and to frame participants' experiences in the wider context of healthcare. Biomedicalization was described by Clarke et al. (2003) as the "increasingly complex, multi-sited, multidirectional processes of medicalization, both extended and reconstituted through the new social forms of highly technoscientific biomedicine". Biomedicalization is driven by and at the same time fosters five key overlapping processes: major shifts in health and healthcare policies and funding; the focus on health itself and elaboration of risk and surveillance biomedicines; technoscientization of biomedicine; major changes in the production and consumption of biomedical knowledge; and transformation of bodies and new individual and collective identities. The results of this study are better understood and explained in the light of this framework as we will explain in the discussion section.

MATERIAL AND METHODS

Study design

This is a qualitative study in which data were collected through 15 semi-structured interviews to explore the experiences of chronic low back pain (CLBP) patients taking opioids to treat their

pain. Individual interviews were analyzed by qualitative content analysis as applied in health sciences research ³⁷.

Participants and Data collection

The study protocol was approved by the Clinical Research Ethics Committee of the “Puerta del Mar” University Hospital (Cádiz, Spain), ensuring compliance with the standards of good clinical practice.

Recruitment and data collection were conducted from April to October 2018. The participants were recruited from the Pain Clinic in Hospital Puerta del Mar. Inclusion criteria for the study were: adults suffering from chronic non-malignant low back pain and receiving long-term treatment (over three months) with opioids. Patients taking opioids for less than three months or with another pain origin than chronic non-cancer low back pain were not included.

All the patients were recruited after a routine physical evaluation in their medical visit to the Pain Clinic. Previously, their medical data, including information on prescribed medications from the records, were evaluated and discussed by the clinician and interviewer. If the person met the inclusion criteria after an analysis of their medical records and their medical visit and physical evaluation, the clinician explained to him or her the aim of the study. All seventeen eligible patients were approached by the clinician. After this initial approach by the clinician, the interviewer met the potential participant and they went to a quieter place in a clinical setting for the interview, before with the participant was shown a letter with more comprehensive information about the study and its aim. The participants were left alone to read and think carefully before giving their written informed consent. When they finished reading it, they had the opportunity to ask questions about the study, after which the interview took place. At this stage, two people rejected the participation, alluding to lack of time. Individual, semi-structured, qualitative interviews following a guide were conducted in Spanish. The guide was based on open-ended questions developed with guidance from the literature regarding chronic pain experiences and factors associated with the use of opioids (Table 2). Aspects related to the origin of their pain, opioid belief, information received about treatment, opioid experience, their family and social support were also of particular interest. If a specific topic that was not included in the first version of the interview guide came to light spontaneously in a specific interview, it was added and asked in the subsequent interviews. Interviews were audio-recorded, transcribed verbatim and anonymized. All names used here are pseudonyms. We conducted

interviews until very similar experiences were described in the last interviews as in the previous interviews.

Analysis

We adopted a constructionist perspective. We analyzed all the interview transcripts following qualitative content analysis as described by Graneheim and Lundman ³⁷. The data analysis was inductive, and thus the category construction was data-driven; no initial hypothesis guided the preliminary coding and subsequent development of categories. However, in the analysis of the results presented in the Discussion section, we followed the biomedicalization framework described above.

Interview transcripts were entered into Atlas.ti 1.0.16 to support the coding process. At the beginning of each interview transcript, a brief log of the interview was written, including information about the time, duration, and the feelings and perceptions of the interviewer during the conversation in order to help with the analysis process. The researcher who conducted the interviews transcribed them verbatim.

To carry out the qualitative content analysis, two researchers read the transcripts independently and assigned codes line-by-line to meaningful pieces of the interview transcripts. Then, the researchers met to compare and refine codes, which were then grouped into categories. The material was grouped into three key categories, which were further validated after re-analysis of all the interviews. Coding maps were used to help with the code grouping and the analysis of relationships between the emerging categories and codes. In the last step, an overarching theme involving these three categories was identified. The analysis was conducted in Spanish and quotes were chosen from this material to be translated into English. All the authors understand both languages and, thus, were able to participate in the whole analysis process.

Our positions as researchers have continuously been discussed in relation to ethical considerations and questions about responsibility. In line with Graneheim and Lundman (2004) ³⁷, we argue that, in qualitative content analysis, interpretation involves a balancing act of providing interpretation while at the same time making sure that our interpretations remain always grounded on the data. By providing a thorough explanation of the analytical process, our intention is to allow the reader to assess the study's usefulness and transferability.

RESULTS

Fifteen people aged from 40 to 88 were interviewed (9 women and 6 men). One participant had completed higher education and the rest elementary education. Four had a declaration of total disability to work, two were on sick leave and nine were retired or unemployed. Thirteen were prescribed a treatment with a strong opioid, one of the two who were taking weak opioids had a PRN order (Table 1 near here).

From the analysis, one overarching theme was developed: “Living with opioids: dependence and autonomy while seeking relief”, which crosscut three categories: “The long pathway to opioids due to the invisibility of pain”; “opioids: from blind date to a long-term relationship”; and “what opioids cannot fix”.

The quest for effective treatment was a fundamental part of the participants’ struggle to cope with the pain, and it involved long-term relationships with the health system. In relation with this, the theme “living with opioids: dependence and autonomy while seeking relief” refers to how navigating the health system meant that the study participants were dependent on healthcare professionals exercising their power to refer them to specialized care to get access to a diagnosis and treatment, including opioids. At the same time, it also meant having, to a certain extent, room to make decisions, to exercise autonomy, despite having little information and meeting professionals that hardly coordinated/communicated with each other.

The two first categories “the long pathway to opioids due to the invisibility of pain” and “opioids: from blind date to a long-term relationship” refer to the journey participants made to get a diagnosis and treatment with opioids, and their experiences during this long and difficult process, which was quite unique for each person. The third category, “what opioids cannot fix”, describes the circumstances and situations experienced by the patients before and after the painful episode started, and how they have influenced the whole process. In this case, opioids do not have any effect since they are not enough to remedy the deficiencies derived from these situations.

The long pathway to opioids due to the invisibility of pain

This first category describes the long and difficult pathway that participants followed from the onset of their pain until getting treatment with opioids. This journey could start as soon as early adolescence (Table 3).

For the participants, the fact that pain “cannot be seen” explained such a lengthy journey to obtain diagnosis and prescriptions. They mentioned numerous consequences of this invisibility of pain in individual and social spheres, as well as in their encounters with the health care system. At the individual level, the invisibility of pain meant that it could be ignored or minimized by those suffering from it. As Alejandro (51 years old, 4 years taking morphine) said, *“mine [pain] was caused by work, by lifting weight, my back started hurting, and... I was walking and limping, and I thought it was...well, nothing. I thought it will go away. By the time I realized and went to the doctor, I was using crutches”*.

In the social arena, the long history of pain, together with the lack of physical signs, could lead, in the view of participants, to indifference or a lack of empathy. As Hugo (52 years old, 5 years taking morphine) claimed, *“my family say that I’m exaggerating”*. Relatives and friends were described as having got used to seeing participants in pain and therefore minimized its importance. Participants described the difficulty in lending credibility to the severity of the problem when there were no physical signs. As Rafael (52 years old, 5 years taking tapentadol) put it: *“They’ve seen me in pain for so long... I think ‘if they could know how much pain I feel’ but they see me every day in the same situation and they’ve become used to seeing me in pain”*.

In relation to the healthcare services, participants described how they had to struggle with healthcare professionals to be believed and have their pain taken seriously, as Laura referred (Table 3). Similar to what happened in the individual sphere, referrals from primary and emergency care to specialized pain services did not begin until the patient’s mobility was severely affected, until the pain manifested itself through physical signs or until they visited the same facility several times without improvement. That led to long waiting times and delays in receiving an appropriate diagnosis and treatment.

Entering the referral system was the beginning of a tortuous journey of hopes and disappointments, a trial/error process that involved trying different treatments with the dream of a pain-free life, as the quote from Lola portrays (Table 3)

The Pain Clinic was commonly the place where the long-term treatment with opioids was established, although in some cases treatment with opioids had started before reaching such specialized services, i.e. in primary healthcare facilities. This relationship with opioids, frequently initiated at the Pain Clinic, is the focus of the next category.

Opioids: from blind date to a long-term relationship

This category portrays beliefs and perceptions of the benefits and drawbacks of treatment with opioids, in addition to struggles to keep autonomy and make decisions while being a long-term patient within the health system.

It was difficult for participants to recall their first contact with opioids, since the common experience of the interviewees was that they had been given little or no information about the new medication they were prescribed. Consequently, it was difficult for participants to distinguish between medications that were in fact opioids and other drugs (Table 3).

When the participants realized that they were being prescribed opioids, they seemed to accept the treatment due to the intensity of pain suffered, despite having the perception that opioids were for terminal diseases or relating them with drugs and addiction (Table 3, Sofia and Lola quotations). Yet, the perception of opioids as a “serious” prescription was maintained over time and the fact that their acquisition is regulated and controlled was mentioned repeatedly in the interviews. There is also a paradox since although some of the participants noticed adverse effects of their medication and they reflected on the difficulty involved in quitting this long-term treatment they weighed in favor of relief. As Sofia (46 years old, 2 years taking oxycodone) said: *“The truth is that they benefited me, I mean, I experienced no strange reactions... well, drowsiness, I am like an animal in hibernation, sleeping the whole day”*. This understating of the effects - drowsiness, in that case - could also be related to the lack of information received from healthcare professionals. As we see in the next quote, Rafael explained commonly experienced adverse effects with opioids like tolerance and dependence without naming them specifically:

“The point is that coincidentally my illness has become worse, and thus, they go parallelly, the increase in medication dosage and the increase in pain, and consequently they are increasing the dosage because my pain is getting worse. The pain I had six months ago is now worse. What’s happening is it’s like my body got used to the treatment.”

As time passed, the participants appeared to start taking a more active attitude towards coping with pain. They described how they had learned ways to relieve the pain, including resting, losing some weight, exercising (e.g. swimming, Pilates, walking) and taking other medication as needed (e.g. muscle relaxants, nonsteroidal anti-inflammatory drugs). As a reaction to the adverse effects experienced, they seemed to become progressively more active in decision-making related to pain management, and less likely to rely exclusively on opioids. In this sense, medication-related decisions were frequently made without consulting the healthcare professionals.

“It was the bad sweating that I suffered... I read the information pamphlet and read sweating was an adverse effect and then I wondered, ‘what if I reduce a little bit the dose? Let’s do an experiment!’ I thought ‘maybe the doctor will get angry with me, but I am going to experiment’, without quitting totally. I thought ‘I am going to take less than what I was told, and I’ll see if I can continue without pain and avoid that unpleasant sweating’ and, right now, indeed, I am taking half of the pill”. Pilar (56 years old, 8 years taking tapentadol)

But these more active coping strategies to reduce pain did not mean total skepticism of opioids. Although the participants complained that opioids had not totally eliminated the pain, there was a common feeling that they contributed to pain reduction. Sofía said: *“I was unable to take a step, and thanks to starting to take morphine, I can now stand up. If I was not taking it, I wouldn’t be doing what I am; I do minimal things but I at least do them.”*

The interviews unveiled that their experience with opioids was strongly intertwined with many other life circumstances that lie far beyond the scope of action of any medication, as explained in the next category.

What opioids cannot fix

This category describes different spheres of the participants’ lives where pain has an impact on a range of economic, familiar and/or social issues that cannot be addressed through opioids (alone). Moreover, these issues may not only be the consequence of pain, but what caused it in the first place.

Besides physical limitations and problems, the emotional sphere was one of the most strongly affected areas, one that opioids could not improve and could even affect negatively. Although in some cases reductions in pain led to a better mood, in others, sadness due to physical limitations and fear of pain was constant. The next quote reflects how pain (and the opioid medication to treat it) had disrupted a participant’s life and hindered them from doing basic daily activities.

“I have noticed changes in my mood, you know? I have a strong personality. I don’t know whether it’s the pill or whether it’s the.... Not being able to move as I wish, not being able to do things the way I would like to. I often feel useless, even with my partner... I cannot even have sex as a normal person would, I’m limited!” Laura (55 years old, 1 year taking tramadol).

In certain cases, these decreases in mood caused by pain resulted in mental health comorbidities among the participants. Sometimes this was exacerbated when participants were told about the chronicity of their illness (Table 3).

To navigate life suffering pain, family support was regarded as essential by the participants. However, at the same time, being dependent on their help because of their physical limitations raised perceptions of being a burden. Moreover, as described in the first category, participants related sometimes feeling neglected, as if their families had got used to seeing them in pain. Roberto (72 years old, 2 years taking tapentadol) explained: *“They help me, everything that needs to be done now it’s done by my sons-in-law, poor them, because I can’t. But you often feel useless; it bothers you that someone is working hard on your behalf, but they are very nice”*.

The women participating in the study, regardless of whether they were on sick leave or retired, did not identify housework and childcare as work, and they mentioned still being the only person responsible for housework despite their disabling pain. In addition, as the Pilar quote shows in Table 3, women refer to the “little things” that their partners do at home as their “help”, showing that housework is not a shared responsibility from the start.

The participants were aware of the importance of maintaining an active social life, and consequently appeared to make an effort to do so. This was easier with people who shared the same pathology, problems and treatment. Lola (41 years old, 8 years taking tapentadol) said: *“I’m part of a Facebook group of people with the same surgery as I had. You can hear some people encouraging others; at night you know that half of them have been awake like you, and you are there... and that cheers you up a little bit. Now, I’m surprised to see how many people are taking opioids; indeed, we all take them as if it was water. It’s much more common than I had ever imagined”*. Outside “pain friends” circles, the experience was different and participants related having felt judged by other people when they disclosed they were taking opioids.

Narratives of hard lives where pain was ‘just’ another added difficulty were a constant in the interviews. Having performed manual labor from a young age was common among these patients, and sometimes the cause of the illness and the pain. Sofía stated: *“I was a cleaner, and they told me ‘throw this in the garbage’ and I pulled the trolley and that was it... because my back creaked and afterwards my back was destroyed from my job as a cleaning woman”*. Likewise, poor working conditions and living with economic difficulties appeared intertwined as a cause and consequence of pain. As Rafael mentioned: *“At home the only income is my salary.*

I have to pay the mortgage, for my children's studies... well, our income is reduced as I'm on sick leave...so I cannot stop working and this situation has led me to a state of anxiety." As is the case with family support, there were also differences between men and women related to economic difficulties. For two men who participated in the study, the pressure of being the breadwinner had negative emotional consequences. For three of the women, being economically dependent on their partners led to them having feelings of helplessness. Ana (41 years old, 5 years taking tramadol) said: *"The point is that I get on well with my husband, but if I did not get on well with him... what could I do? I'm unemployed, I don't have anything, (she gets emotional) "my God".*

DISCUSSION

The findings of this study show how the experience of relieving pain is a constant struggle among people who suffer from it. Opioids become a way of reducing pain, facilitating physical and social functioning and making a more independent lifestyle possible. However, these feelings of independence about physical or social functioning are in conflict with concerns of dependence on the medication.

Our results described how the participants' experiences were severely influenced by the invisibility of their pain, in the same line as findings from previous research³⁸⁻⁴⁰. In this sense, the absence of a uniform classification and a validated diagnostic tool in this type of pathology hinders the standardization of treatments that biomedicalization has brought to other diseases, leading to uncertainty in the treatment and diagnosis of the patient, and making it very much dependent on the individual perception of the treating physician^{40,41}. Thus, as we have seen in our results, the choice of where to refer patients and how to treat them is a lengthy trial and error process, which is certainly not ideal, and opens the door to disparate access to health care.

In this study, the overwhelming majority of participants eventually treated in the Pain Clinic after lengthy periods navigating through the healthcare system were employed in unskilled jobs and reported having a basic level of education. We argue, based on the discourse of biomedicalization⁴², that this overrepresentation of patients from lower socio-economic backgrounds in our study is because the quest for a diagnosis and treatment could presumably be "easier" and "shorter" for those who can afford private medical care and can skip the mutual referral system between the GPs and specialists of the public health system. The increase in stratifying fee-for-service options, which is another characteristic of biomedicalization, enables

the more wealthy to address their illness, circumventing waiting times for medical procedures and obtaining access to multidisciplinary intervention in the biological, psychological and social aspects of their chronic pain condition ⁴³.

In relation to experiences with opioids, our findings show that opioids were insufficient to relieve all the pain, as examples of limitations to daily life because of pain were an important part of the participants' narratives. However, the participants' perception was also that their physical functioning and quality of life had improved thanks to opioids. These contradictions between perceived improvement and narratives of severe limitations were recurrent in the participants' accounts. As other authors have shown ¹⁸, due to a lack of information or misinformation, patient expectations regarding the results they can expect from this treatment may be unrealistic. In line with this, the difficulties the participants found to identify side effects, tolerance or dependence were also noteworthy. Exemplifying the heterogeneity in the production, distribution and access to biomedical knowledge that is part of biomedicalization, the majority of the participants stated that they had looked on the internet to be informed about opioids and their consequences, and in many cases developed individual strategies to deal with the side effects they experienced. Having to look oneself for information about the treatment prescribed reflects a shift in responsibility for care practices, which is put increasingly on healthcare-users, this change being another essential component of biomedicalization ⁴². Even if access to medical knowledge is improved thanks to new technologies, the ability to benefit from that information depends strongly on individual health literacy levels. According to a report published by the WHO in 2013 ⁴⁴, more than half of the Spanish population have inadequate or problematic health literacy levels ⁴⁴. Furthermore, the population with a lower social status have much higher proportions of limited health literacy levels ^{45,46}. In addition, increased responsibility for their own healthcare driven by biomedicalization processes leads to self-blame for any health problems that arise. As seen in some of the quotations of the participants, they blamed their pain on things they have done, like pulling too much weight or waiting too long to seek medical care instead of placing the blame on their working conditions when evidence shows that unskilled workers have the highest prevalence of musculoskeletal disorders, a large proportion of which can certainly be attributed to working conditions ⁴⁷.

Finally, another basic process of biomedicalization is the production of new identities and reframing of old ones by technoscientific means. In this sense, the social role and identity of chronic patients for whom no cure is available despite all the technoscientific advances remain a challenge due to the invisibility of pain. In the social arena, the participants of our study felt

stigmatized in several ways. They felt neglected due to the invisibility of pain. Many patients with CP do not present any visible symptoms and remain stoic when they feel pain, resulting in a lack of empathy from friends ⁴⁸. In addition, the participants felt stigmatized because of the treatment with opioids. Ljungvall et al ²⁶ described how participants experienced being stigmatized because of their repeated contacts with medical care workers, who see them as drug-seeking behaviors. However, in our study, the participants experienced this stigmatization by relatives and friends who expressed many concerns and prejudices about opioids. The negative consequences of “double” or “layered” stigmatized conditions - “CP sufferer” and “drug addict” – have also been described by Dassieu et al. ³¹, who suggest that being doubly stigmatized reinforces people's isolation as well as their experience of loss of dignity. Interestingly, in our study, the participants referred to sharing their experience of CP and opioid treatments with ‘pain friends’, among whom treatment with opioids was common. Peer support has been shown ⁴⁹ to reduce social isolation, encourage shared experiential learning and foster psychosocial well-being. Thus, “taking charge” of their health, understood in biomedicalization as responsibility for care practices, by means of active coping strategies such as maintaining an active social life with “pain friends” was crucial for the health of the participants, as reported in the literature ¹⁸.

As previously described ^{28,50}, family support was also very important for the participants with regard to the management of their pain. Some, however, considered themselves to be a burden due to their physical disability. This feeling could result from a sense of inequity or imbalance if they perceive that what they receive outweighs what they provide ⁵¹. In addition, some participants described feelings of depression and uncertainty, as well as a decreased sense of autonomy and/or self-confidence because of both physical and economic dependence. These worries emerge strongly in this study. As a result, physicians often find themselves trying to bridge the gap between the chronic pain patient's expectations for effective pain relief and the harsh biomedical reality ⁵². However, medication, opioids in these cases, is not enough to solve problems of another nature that in some cases predated the pain.

Clinical implications

Greater awareness should be raised among health care professionals about the experiences of patients with CP to counterbalance the negative effects of the invisibility of pain such as the lack of credibility given to symptoms expressed by patients and delays in access to diagnosis and treatment. This would shorten and improve patients' relationship with health care services.

Regarding information about long-term treatment with opioids, there is a need to improve the quantity and quality of information provided to patients. Furthermore, health care professionals should be aware of the extended use of alternative information sources like internet or peers among patients who experience CP, to ensure they are able to assess the credibility of the information they access and are able to understand and make use of this information, i.e. to ensure they have sufficient health literacy levels.

Finally, an interdisciplinary approach and health care team that includes social workers and psychologists is essential to address all those spheres of life affected by and affecting CP experiences and where opioids have little or no effect.

Methodological considerations

As previously described, several steps were taken to strengthen the trustworthiness of the findings. These do, however, need to be interpreted with some limitations in mind. Concerning transferability, it is important to consider the context where this study was conducted: a group of individuals with chronic pain, treated in a Pain Clinic of the Spanish healthcare system. With this in mind, we consider that the results from this study could be relevant for understanding the experiences of people with CP who are taking long-term treatment with opioids in other countries with similar socio-cultural aspects and health care systems, since the consequences they face and concerns they have about opioids may be the same.

Regarding credibility, we chose participants with different sex/gender, ages, and experiences to increase the likelihood of shedding light on the research question. What is more, the open-ended questions made it possible to share both positive and negative experiences. However, people who were at the beginning of the illness process may not have been reached, since we recruited participants via the Pain Clinic. Nonetheless, as we discuss in this study, CP is an illness that implies a long and difficult process before being diagnosed and treated. Thus, opioids as a treatment are usually prescribed to those who have been suffering pain for a long-term period.

Another limitation of this study is that, although the results suggested gender differences in the patients' experiences with both CP and its treatment with opioids, the data were not rich enough to support a deep analysis and the elaboration of conclusions. Further research with this aim is required.

CONCLUSIONS

The participants' experiences were strongly shaped by the invisibility of pain, which led to a long-term relationship with the health care system and different forms of stigmatization. The participants made up for the limited information received from health care professionals by surfing the internet or asking peers. Yet, they showed limited knowledge about side effects and the long-term consequences of the treatment.

The burden of social determinants of health was increased by CP and at the same time a source of complications in CP experiences.

Table 1. Characteristics of the sample

	Gender	Age	Income/Occupation	Years with pain	Under opioids' treatment	Opioid currently prescribed
Julia	Female	88	Retirement (Housewife)	15	1 year	Tapentadol
María	Female	40	Total permanent disability (Administrative assistant)	22	8 years	Tapentadol
Laura	Female	55	Sick leave (Administrative assistant)	14	1 year	Tramadol (PRN)
Juan	Male	72	Retirement (accountant)	4	4 years	Tapentadol
Pilar	Female	56	Unemployed (Housewife)	13	13 years	Tapentadol
Lola	Female	41	Total permanent disability (Administrative assistant)	8	8 years	Tapentadol
Carlos	Male	66	Retirement (bricklayer)	2	6 months	Tapentadol
Rafael	Male	52	Sick leave (watchman)	5	5 years	Tapentadol
Ana	Female	41	Unemployed (Housewife)	7	5 years	Tramadol
Leticia	Female	72	Retirement (hairdresser)	48	4 years	Tramadol y Tapentadol
Sofia	Female	46	Total permanent disability (Cleaner)	2	2 years	Oxycodone
Alejandro	Male	51	Total permanent disability (bricklayer)	9	4 years	Morphine
Roberto	Male	72	Retirement (mechanic)	"Long time ago"	2 years	Tapentadol
Carmen	Female	80	Retirement (cleaner)	30	"many years."	Tramadol
Hugo	Male	52	Unemployed (carpenter)	5	5 years	Morphine

Table 2. Interview guide used for the semi-structured interviews.*Exploring pain*

How did the pain start?

Exploring prescription of opioids and information

Can you tell me about how you started taking opioids?

How did your doctor suggest taking these medications?

How did you react when your doctor told you that you will be taking an opioid treatment?

What was your opinion about opioid medications before taking it? And now? Has your opinion changed?

Were other alternatives considered? Which ones?

What type of information about opioids have you received?

What is your opinion about the information that your doctor gave you about the treatment?

Have you sought information through other means? Which ones?

Daily life and opioids

Can you describe a usual day in your life?

Since you started this treatment with opioids, have you changed your daily activities?

Since you started this treatment with opioids, could you describe how your health is?

Could you describe your mood since you started this treatment with opioids?

Do you think that opioids cause side effects? How?

Taking opioids

Have you ever tried to stop or decrease the opioid dose? Why? How was the experience?

Since you started this treatment, have you needed to increase the dose? Do you think you would have needed to increase the doses? Why?

What is the best way to relieve your pain?

Social relationships and work

How is your social life since you are under an opioid treatment?

Can you describe the relationship with your family? Has this relationship changed since you are under treatment?

Can you describe your working life?

Final questions

How is your experience with opioid treatments In general?

Would you like to add anything else?

Table 3. Quotations illustrating categories and theme.

<p>Theme: “Living with opioids: dependence and autonomy while seeking relief”</p> <p>Category: “The long pathway to opioids due to the invisibility of pain”</p> <p>Ana, 41 years old, 5 years taking tramadol: <i>“since I was a kid, I’ve always had back pain. I had to come frequently to the hospital, always with “lumbago”, mainly “lumbago”.</i></p> <p>Carlos, 66 years old, 6 months tapentadol: <i>I have had this problem for at least 2 years, and it has been getting worse and worse... I wanted the doctors to see me, but there was a long waiting list for the specialist. I had to go to the emergency room because I couldn't take it anymore. Over and over again to the emergency room... and again a dropper, only a dropper... until finally the neurosurgeon saw me and said: something must be done here, and he sent me here to the Pain Clinic.</i></p> <p>Rafael, 52 years old, 5 years taking tapentadol: <i>(talking about a previous health problem in the eye) “well, it was more visible, the eye was really red, red, red, and people asked me “What happened? Did you hit something or what did you do?” [...] You could see the surprised and shocked faces. But now (with Chronic Pain (CP))... they see me so fine, so healthy, and in my inside, I am dying with pain”.</i></p> <p>Lola, 41 years old, 8 years taking tapentadol: <i>“My parents took me first to the emergency room, and they injected me with morphine, and sent me home in an ambulance [...] The following day it was the same. Another injection and go home. Then, they told me that I needed surgery because all my lumbar area was calcified. Then I could feel something strange... and they prescribed (small pause) morphine, and each time the dosage was increased more, and more... and there was no pain relief. They told me there were two possible big issues with my type of surgery: instability remaining in the backbone or leaving residues of spinal discs, and I had both”.</i></p> <p>Category: “Opioids: from blind date to a long-term relationship”</p> <p>Laura, 55 years old, 1 year taking tramadol: <i>“The doctor told me: ‘I’m going to prescribe you this medication that I think is going to help you’. I found out later that tramadol was an opioid, when I searched it on the internet, and people told me: ‘uh, that medicine has this and that...’ and I said, ‘that much?’ ‘yes, yes, it’s like morphine, a derivative’. After this, I saw what it was. But my doctor didn’t tell me anything.”</i></p> <p>Sofia, 46 years old, 2 years taking oxycodone: <i>“I didn’t know what morphine was. I had heard that it was for drug addicts, that’s the truth... I didn’t know... That’s what I have always heard in my house. I knew there were patches and all that stuff, but I didn’t know for what exactly.</i></p> <p>Lola, 41 years old, 8 years taking tapentadol: <i>“I was very wrong [...] I remember that morphine was used with my grandfather before dying to relieve his pain and all that stuff, so I never thought I would have to take it as they say “as an outpatient treatment, at home.” I didn’t think it would be like that”.</i></p>
--

María, 8 years old, 8 years taking tapentadol: *"The morphine has caused me... I sleep with a CPAP because of the dryness that morphine left me. It caused me sleep apnea. It's left many side-effects apart from my illness because all the medication that I have been taken."*

Ana, 41 years old, 5 years taking tramadol: *"It's true that opioids must have some effect, because I remember that once I ran out of them ... and I do not know if it was a day or two without taking them, and look, I was a physical wreck. I had to lie in bed [...] When I bought and took them, it made me "Boom!". I rush out to the shops! My husband was shocked! I said: "the pill, look what the pill has done to me".*

Category: "What opioids cannot fix"

Ana, 41 years old, 5 years taking tramadol: *"For some time I had to take anxiolytics. The doctor said that my problem had no solution, that I was going to be in pain forever, and I fell apart. But it's true that I had no other option. I always try to say to myself: 'no, come on, I'm not going to cry'. This is what I have and that's all there is to it. Your mind is the one that has to say: 'hey, we stop here, I will not cry'.*

Pilar, 56 years old, 8 years taking tapentadol: *"I have little help to be honest. I often get angry with him [her husband] because of that. All the work is for me. Well, if I'm cleaning, of course he helps me, but the housework... he doesn't... he hangs out the washing, he helps me with little things like that, he helps me making the bed and that's all.*

María, 8 years old, 8 years taking tapentadol: *"I speak to my very close friends and I have to explain that it's morphine and that this is what I need for my chronic pain. The society is not... not well informed; it's seen like... phew... so bad, she's dying or it must be bad if she is taking morphine, and it's not like that".*

Lola, 41 years old, 8 years taking tapentadol: *"My family has been my lifesaver. Without my father and my mother... look, I am giving more importance to them than to my partner. During the day, my partner is not with me. He cannot stop working to stay with me... it is understandable with just one salary for both of us. If he stops working, we cannot live."*

GENERAL DISCUSSION

Throughout the 4 studies that compose it, this doctoral thesis addresses diverse aspects and consequences of the use of opioid treatment in recent years. To this end, we first analyzed the prevalence of the use of an opioid treatment in chronic pain patients. Secondly, taking into account the consequences of the use of opioids, we studied the mortality related to their use. Then, we further investigated the point of view of the general Spanish population about the treatment of CP with opioids. Finally, we took a deeper look at the experiences of people that are taking opioids to treat their pain. The conclusion can be drawn that the appropriate use of opioids is a way of reducing pain. However, it presents a constant struggle with concerns related to dependence and addiction to the medication, sometimes related with the death of the patients.

In the first paper, we present a systematic review following a rigorous methodology that analyzed the information published about the prevalence of opioid use in patients with CNCP and the main factors related to the use of opioids. The results obtained reveal important differences in the prevalence that are related with the length of the treatment, the occasional use of opioids being more prevalent than their long-term use.

The lower prevalence found in patients with longer-term treatments seems reasonable if we take into account the prescribers' concern about the risk of addiction and the improper use of these drugs by some patients ¹⁰⁰. The results are consistent with those found in the third study of the thesis about the perspective of the Spanish population regarding opioids. These results highlight the concerns about the risk of addiction, with the notable existence of a group of people that had taken opioids in the past, but would refuse to take them again, arguing the difficulty in stopping taking this drug. Another reason that would justify the lower prevalence of the long-term use of opioids is the active attitude of the patient coping with pain ¹⁰¹. As our fourth study about the experiences with opioids of the patients shows, as time went by, the participants became progressively more active in decision-making related to pain management and less likely to rely exclusively on opioids, since they had learned other ways to relieve the pain, such as losing weight, exercising and taking other medication as needed.

We could think that the prevalence of the use of opioids is greater when the prevalence of CP is higher ²⁹. However, comparing the results from different countries, this hypothesis was not

confirmed, since there are different cultural, social, political, and historical factors, as well as others related to advertising and marketing ^{4,62} that could influence the use of opioids for pain relief. In this regard, Bosetti et al. ⁶⁴ have reported that Southern and Eastern European countries have the lowest consumption, which would imply, a priori, a lower risk. These results are consistent with those presented in the second paper of the thesis where, even after standardization, the rates of opioid-related mortality between Spain and the USA are clearly different, these being 8–12 times higher in the USA than in Spain, depending on the year.

Regarding factors associated with the use of opioids, we found that patients without insurance or those who had non-commercial insurance presented greater use of opioids. The type of medical insurance can influence the way pain is approached and consequently determine the use of opioids. Some studies have shown ^{102,103} that patients with private insurance receive more immediate attention with a multidisciplinary approach, leading to better results and a decrease in the use of analgesic treatment. In line with this, in our fourth study, carried out in the public Pain Clinic, we found that the vast majority of participants had unskilled jobs and a basic level of education, and they reported obtaining a diagnosis only after lengthy experiences of navigating through the healthcare public system. We argued that the difficulty in obtaining a diagnosis and treatment could presumably be exacerbated for those with a lower educational and economic level who cannot afford private medical care and can avoid the mutual referral system between the GPs and specialists of the public health system.

Gender is another factor related to opioid use. The results of our systematic review showed that opioid use was more prevalent among young men. Additionally, this group also showed the worst evolution of opioid-related death in the second paper. According to the Spanish Report on alcohol, tobacco and illegal drugs of 2017 ¹⁰⁴, the main psychoactive substances involved in the deaths in recent years in Spain are hypnotosedatives and opioids, reported in over half of the deaths. However, the report does not specify if opioids were the main cause of death, a causal relationship between their use and the main cause of death being difficult to establish. Nevertheless, historically, it has been shown that addiction to opioids has always been higher in men ¹⁰⁵.

As we have seen in the group containing young men, an increase in opioid-related death has also been observed in the group of women over 55. We argued that they have more risk of suffering side effects such as respiratory depression often related to eventual death ¹⁰⁶, since

chronic conditions are more prevalent in women of these ages ¹⁰⁷, opioids being one of the most common treatments ¹⁰⁸. Although there is limited information about gender differences in the risk factors related to opioid use ¹⁰⁹, what is known from clinical studies is that women are more sensitive to both dosage and type of medication ²¹.

The willingness to accept treatment with opioids was analyzed in the third paper, identifying three different profiles. One group had a positive vision of opioids, had more confidence in their physician when prescribing these drugs, and were less concerned about their adverse effects. The other two groups were more worried about the side effects of the opioids and less willing to take them upon medical prescription. One of these groups showed more deep-rooted opiophobia. In spite of this, many patients who see opioids as a last resource, say they would eventually be willing to start treatment if the pain became severe ¹¹⁰. In this vein, when we analyze the experiences of people taking opioid treatments in the fourth study, the participants admitted to having accepted their treatment due to the intensity of pain suffered, even though they had previously related opioids to terminal diseases or to drugs and addiction. In this sense the pain-relieving effects tipped the balance in favor of patients accepting the treatment with opioids despite their concerns.

Taking a more in-depth look at the experiences of people taking an opioid treatment, the fourth study of the thesis shows that relieving pain is a constant struggle for people who suffer from it. These experiences were severely influenced by the invisibility of their pain and the long and difficult process to get a diagnosis. Participants were dependent on healthcare professionals exercising their power to refer them to specialized care to get access to a diagnosis and treatment, including opioids. At the same time, to a certain extent, they had room to make decisions and exercise autonomy, despite the lack of information available to them. Other authors have shown ⁷⁷ that this lack of information or misinformation can also lead to unrealistic patient expectations regarding the results of this treatment. In this vein, concerns regarding adverse effects and unrealistic expectations of the treatment goals can be considered the most important consequences of the lack of information received.

The support of relatives and friends is essential for CP patients, as shown in the fourth paper. However, interestingly, the participants preferred to share their experience of opioids with 'pain friends', who were usually receiving the same kind of treatment. The stigmatization of CP people is revealed in the literature, which sought to identify the 'pain-prone personality' ¹¹¹. In this

sense, the patients in our study stated feeling stigmatized for taking opioids too, since relatives and friends showed concerns and prejudices about this treatment. In this vein, in the third paper, we saw how the general population related opioids to “illegal drugs” such as heroin or cocaine and drug abuse. These types of beliefs could result in a lack of empathy and stigmatization for CP patients consuming opioids, as reflected in the patients’ discourse.

Family support was very important for helping the participants with the management of their pain. Some patients, however, may consider themselves to be a burden for their family due to their physical disability ⁴³. In addition, some participants described feelings of depression and helplessness, as well as a decreased sense of autonomy and/or self-confidence because of both physical and economic dependence. As a result, physicians often find themselves trying to bridge the gap between the chronic pain patient’s expectations for effective pain relief and the harsh biomedical reality ¹¹². However, medication, opioids in these cases, is not enough to solve problems of another nature that in some cases predate the pain.

To sum up, as shown throughout the thesis, CP and its treatment are intertwined with different spheres of the patients’ daily life. Each patient suffering pain has to go through a hard process of legitimating their pain in their social context ¹¹³, which could result in feelings of sadness and uncertainty ⁴⁶. Thus, pain has an impact that cannot be addressed through opioids alone; rather, a more comprehensive approach to the illness is required.

Finally, it is worth remembering here some limitations found throughout the thesis. The specific limitations of each study have already been mentioned in each manuscript. However, some general limitations of the thesis are worth discussing in a bit more depth. The combination of aims and methods made it impossible to work with the same population. We have argued that this can also be seen as a strength, since that let us carry out a thesis with a broad vision. Another limitation is that the third study about the perspective of the general Spanish population was conducted before the United States epidemiological alert was pronounced, which could have had an impact on the results. This study was conducted in the context of Spain and thus the transferability to other populations should be done with caution. However, it showed similar results to other nearby countries. Furthermore, the description of the methodology is transparent enough so that other authors are able to determine the transferability and applicability to other countries.

CONCLUSIONS

In view of the results obtained in the different studies, the following conclusions can be drawn:

From paper 1:

1. The prevalence of opioid use in patients with CNCP varies depending on the duration of treatment and the population analyzed, the prevalence being much higher when opioids are prescribed for occasional rather than long-term use and when the analysis is based on clinical studies or health registries rather than on the general population.
2. A greater use of opioids was observed in men, younger individuals, patients receiving prescriptions of different kinds of drugs, patients with a pain-related disability and in those who suffering more CP conditions.
3. The prescription of opioids was higher in patients without insurance or with non-commercial insurance compared with those with private insurance.
4. Race was also related to the use of opioids, non-white and Asian patients being less likely to receive opioids than non-Hispanic white patients.

From paper 2:

5. The crude rate of ORD per 10⁵ inhabitants has changed from 1.68 in 2008 to 2.25 in 2017 in Spain, with around 30,000 years of life lost per year, middle-aged men and women over 65 the most affected groups.
6. The standardized rates of ORD in the US population are 8–12 times higher than those in Spain.
7. An opioid overuse crisis does not seem a likely scenario in Spain. However, it is a social problem that requires special health surveillance, particularly in middle-aged men, and women over 65.

From paper 3:

8. There is a lack of knowledge of opioids in the general Spanish population. The side effects of these drugs are the most feared aspects associated with their use in the treatment of pain.
9. There are three different profiles of people regarding their point of view towards opioids, which largely depends on educational level, age, and previous contact with opioids.
10. The different perspectives regarding the use of opioids to treat pain should be taken into consideration by physicians when informing patients in order to promote their correct use, and to prevent their misuse in particular.

From paper 4:

11. The participants' experiences were strongly shaped by the invisibility of pain, which led to a long-term relationship with the health care system and different forms of stigmatization. The participants made up for the limited information received from health care professionals by surfing the internet or asking peers. Yet, they showed limited knowledge about side effects and the long-term consequences of the treatment.
12. The burden of social determinants of health was increased by CP and at the same time was a source of complications in CP experiences.

ABSTRACT

Objective: To investigate the evolution of opioid-related mortality and potential years of life lost in Spanish general population from 2008 to 2017. To evaluate the differences between Spain and the US.

Methods: A descriptive study using retrospective annual data from 2008 to 2017 in Spanish and US general population. Information on the population and opioid-related deaths stratified by age and sex was obtained from Spanish National Statistics Institute and the Centers for Disease Control and Prevention (CDC) WONDER Multiple Cause of Death Database, according to the ICD-10 codes. Years of life lost, crude and standardized mortality rates are reported and compared with the results in US.

Results: Crude rate of opioid-related deaths per 10⁵ inhabitants has changed from 1.68 in 2008 to 2.25 in 2017 in Spain, with around 30,000 years of life lost per year. The most affected groups were middle-aged men and women over 65, and the main cause of death was accidental poisoning. The standardized rates per 10⁵ inhabitants across the years were between 1.19 and 1.62 in Spain and between 11.17 and 20.68 in the US population.

Conclusions: An opioid overuse crisis does not seem a likely scenario in Spain. However, it is a social problem that requires special health surveillance, particularly in middle-aged men and women over 65.

KEYWORDS

Opioid; mortality; years of life lost; Spanish population; US population

Introduction

The prescription and consumption of opioids have changed in many countries in recent years as it is becoming a serious health problem in some cases^{1–6}. According to the World Drug Report⁷ 2017, 29.5 million people globally suffer from drug use disorders, being opioids the most harmful. The United Nations has warned of an opioid overuse crisis in the USA in 2017, although this is not the only country in which its consumption has increased¹. In Europe, Bosetti et al.² reported an increase in opioids consumption, with relevant differences between countries. Particularly, these authors observed the highest consumption in Western/Northern European countries and the lowest consumption in Southern/Eastern countries. Some authors^{2,3} identified an upward trend similar to the USA. Although in the country where the consumption is the highest in Europe (Germany), it is approximately half of the level in the United States³. Despite this, a crisis similar to the US is anticipated in other countries such as the United Kingdom in 5 or 10 years⁴.

In Spain, data reported by Garcia del Pozo et al.⁵ in 2008 revealed a huge increase in opioids consumption at the end of the 20th century and the beginning of the 21st century. More recently, The Spanish Agency for Medicines and Health Products quantified the increase from 7.25 Defined Daily Dose (DDD) per 1,000 inhabitants⁶ per day in 2008 to 13.31 in 2015, which represents an increase of 83.59%. However, it is not clear if the situation has worsened in recent years, and there is currently a debate in the scientific community about whether Spain presents a similar trend to the United States, and if we are on the way to a possible overuse crisis.

The aforementioned crisis is not something to be taken lightly, as higher doses of medically prescribed opioids may lead to opioid overdose⁸. This finding challenges the traditional idea that opioid overdose is related to non-medical users⁹. In addition to overdoses, many of the problems associated with the use of opioids, such as addiction, abuse or dependence^{4,9–13}, greater physical and psychological comorbidities^{8,14–18}, an increase in opioid-related mortality and potential years of life lost^{4,19}, have been reported. Some

authors even report that the risks of opioids outweigh the benefits^{4,20}, and the opioid abuse can have clinical and economic consequences in the society, including patients, health care professionals, and the government¹⁴.

Meyer et al.¹⁴ have estimated a cost of \$55.7 billion attributable to prescription opioid abuse in 2007 as well as an increase of 124% in the rate of unintentional overdose deaths. This increase has been observed by other authors, particularly in the USA and Canada^{19,21}, being a problem that affects especially people aged 25–44²¹. This fact aggravates the situation in terms of early loss of life. Few studies have reported the data on years of life lost (YLL), either globally²² or in the United States specifically^{10,19}, where it has been estimated at 830,652 YLL among people younger than 65 years in 2008. However, to the best of our knowledge, there are no studies in Spain analyzing this, even though YLL is an indicator of great importance in this context, as it quantifies the costs of opioid-related deaths (ORD).

As the situation in the USA has been described as alarming, and there is evidence that some countries could be on the same path, it is important to know the situation in a country like Spain, where an increase in opioid consumption has been observed, and a similar tendency might be plausible. Replicating in Spain the results obtained by Gomes et al.¹⁹ in the US would allow us to compare the situation and can prevent a possible overuse problem.

In view of the above, we aimed to investigate the evolution of opioid-related mortality and potential years of life lost in Spanish general population from 2008 to 2017 and to compare it by gender and age. We also aimed to know the differences between Spain and the USA.

Methods

This is a descriptive study using the retrospective annual data from 2008 to 2017 in the Spanish general population. It is based on the methodology previously used by Gomes et al.¹⁹ in the USA to compare populations.

Information on the population and ORD stratified by age and sex was obtained from the Centers for Disease Control and Prevention (CDC) WONDER Multiple Cause of Death Database for the USA²³, and the Spanish National Statistics Institute (INE, for its acronym in Spanish) for Spain²⁴.

The INE carries out the "Statistics of deaths according to the cause of death²⁵" following the criteria established by the WHO in the International Classification of Diseases (ICD-10)²⁶, which includes more than 12,000 diseases. This statistic provides information on mortality according to the basic cause of death and its distribution by sex and age, among other factors. A similar methodology is used by the CDC.

From these data, and according to the ICD-10 codes²⁶, we retrieved information on ORD specifically due to accidental poisoning (X40–X44), intentional self-inflicted poisoning (X60–X64), aggression (X85), and poisoning of not determined intention (Y10–Y14).

For each year (from 2008 to 2017), we report stratified (by sex and age) data on number of ORD, crude and standardized rates of ORD per 10⁵ inhabitants, years of life lost

(YLL), YLL per 10⁴ inhabitants, number of deaths by type of opioid-related death. Crude rate of ORD is defined as the quotient between the number of ORD and the total population, expressed in terms of number of deaths per 10⁵ inhabitants. YLL are defined as the sum of the remaining years that a person who has prematurely died due to opioids has not lived, that is, the sum of the difference of life expectancy and the age of death of each person who has prematurely died due to opioids. Type of opioid-related death is a qualitative variable classifying the deaths in accidental poisoning, intentional self-inflicted poisoning, aggression, and poisoning of not determined intention. The data presented are tabulated in absolute terms and crude rates. We report the number of deaths by type of death and year in Spain, for the total population, men and women separately, in bar plots.

The evolution over time of the standardized rates of ORD in total population, men and women, is presented in a line chart for both Spain and the USA. For this comparison, we standardized the data taking into account the different distribution of the two populations by ages. For this standardization, the direct method was used: the rate of each stratum in each population was applied to the world standard population provided by the WHO²⁷ to obtain data on the expected deaths, which were subsequently added and divided by the total standard population to obtain the standardized rates per 10⁵ inhabitants. We report these standardized rates in a line chart. All the analyses and figures were performed using the software Excel 2016.

Results

Opioid-related deaths and years of life lost in Spain due to opioids in the period 2013–2016

Between 2008 and 2017, a total of 8506 people died due to opioids, including accidental poisoning, intentional self-inflicted poisoning, aggression, and poisoning of not determined intention (Tables 1 and 2). The cost, in terms of YLL, was 290,093.33 years (Tables 3 and 4).

The crude rate of ORD per 10⁵ inhabitants in the whole population has fluctuated (around 2) over the years (from 1.68 in 2008 to 2.25 in 2017), showing a slight upward trend in men from 2011 to 2017, and in women in the whole period. Crude rates in men are always above crude rates in women (around 1 point above) (Tables 1 and 2).

The most affected age groups were, in almost all the cases, 35–44 and 45–54, but the increase of the crude rates in the group of 65 or more years (from 1.25 in 2008 to 3.8 in 2017) is remarkable. In this regard, we observed differences between men and women, with men most affected in the age group 35–54, and women in the age group over 65 (Tables 1 and 2).

Regarding the YLL, we further observed a fluctuant situation, with a minimum of 24,497.35 YLL in 2011 and a maximum of 32,648.99 in 2016 in the whole population (Tables 3 and 4). Nevertheless, it was different between men and women. In particular, men lost more years of life, even more than twice than the women in most cases. The largest amounts of YLL were observed in the age group 35–44 (Tables 3 and 4).

Number of deaths by the type of opioid-related death and year

Most of the deaths had a well-defined cause, with only a few cases due to poisoning of not determined intention (Y10–Y14). In addition, as the years went by, the number of indeterminate cases decreased. Aggression (X85) was the least frequent cause of all (Figures 1(A,B)).

In the total population, the main cause was accidental poisoning, followed by intentional self-inflicted poisoning. When analyzing by sex, the number of deaths due to intentional self-inflicted poisoning was similar in men and women, but a substantial difference in accidental poisoning was evident. Specifically, the number of deaths was higher in men compared with women (Figures 1(A,B)).

Comparison of opioid-related mortality between US and Spanish population in 2016

After the standardization of the rates, we observed a better situation in Spain than the USA (Figure 2). In the total population, the standardized rates per 10⁵ inhabitants across the years were between 1.19 and 1.62 in Spain and between 11.17 and 20.68 in US population. This difference was even more evident for men, and slightly lower (but still relevant) for women. A greater increase in US standardized rates in

recent years was observed, compared to the slight increase in Spain after standardization. (Figure 2).

Discussion

In this study, we have analyzed the ORD in terms of the evolution of opioid-related mortality and potential years of life lost in Spain in the previous years. We have performed a comparison between Spain and the USA. Generally, our results reflect a better situation in Spain than in the USA, although we cannot ignore the upward trend in the opioid-related mortality and the years of life lost.

Specifically, we found between 691 and 1049 deaths per year. Given the data on the considerable increase in the prescription and consumption of opioids previously reported^{5,6}, a greater increase in associated mortality could be expected; however, the increase is not a significant reason for concern.

The worst evolution has been observed in men in the study of Gomes et al.¹⁹, and this pattern is repeated in the rest of the results. Gomes et al also point out that the burden of ORD is higher among men, and our results confirm that in Spain as well. The number of YLL is worrisome in the whole population, but especially in men. According to the Spanish Report on alcohol, tobacco and illegal drugs²⁸ 2017, the main psychoactive substances responsible for deaths in recent years are hypnotosedatives and opioids, followed by

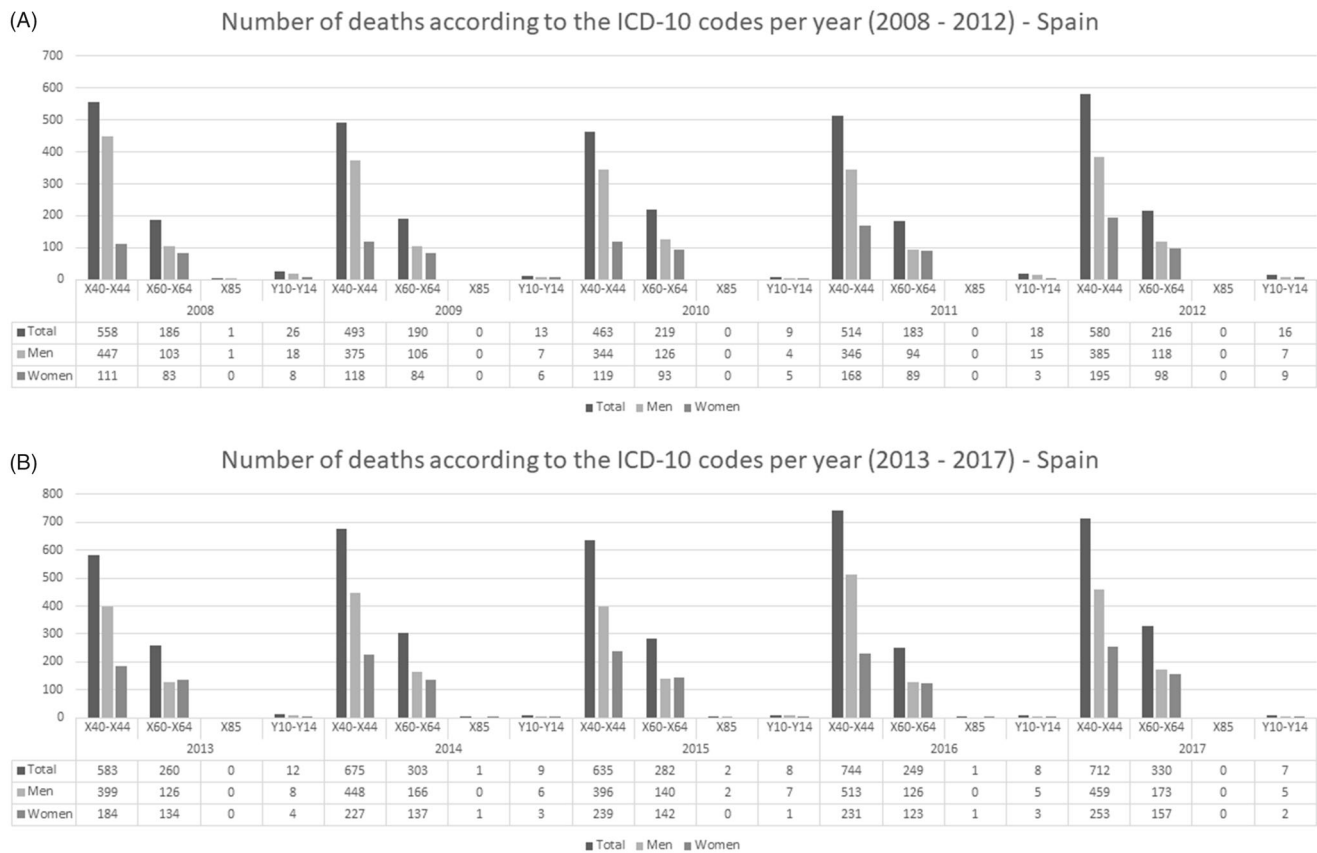

Figure 1. (A) Number of deaths according to the ICD-10 codes per year (2008–2012) – Spain. (B) Number of deaths according to the ICD-10 codes per year (2013–2017) – Spain. Abbreviations. Figure 2. Comparison of the evolution of the standardized rates of opioid related deaths (ORD per 10^5) in Spain and US by gender.

cocaine and alcohol, the latter in a lesser proportion. In more than half of the deaths in which toxicological information was collected, opioids were involved. However, the report does not specify if it was the main cause of death. In any case, this means that we must pay special attention to the consumption of opioids, as these are involved in many deaths, and our data identify these as the main cause of death. Historically, addiction to opioids has always been higher in men. In addition, it has been shown that men are more likely to increase the dose of opioid therapy compared with women²⁹, which is in line with our results. However, recently, there is more controversy in this regard, with higher levels of addiction in women in some cases^{30–33}.

Regarding the differences by age, we observed that the most affected ages were 35–54, similar to the US population¹⁹. However, in the group over 55 in the USA, an increase in the rates has been observed. This was also observed in our data in Spain in some of the studied years, mostly in women. It could be argued that this is due to the greater use of these drugs in cases of terminal diseases, although it must be taken into account that the registered main cause of these deaths is not the disease, but the opioid. Besides, this would not explain the gender differences. The prevalence of chronic pain is higher in women of this age group³⁴, with opioids being one of the most used treatments for pain³⁵. A systematic review published on sex differences in opioid effect on pain³⁶ has found that side effects such as emesis and respiratory depression, the latter often related to an eventual death³⁷, are more pronounced in women. However, there is limited information on gender differences in opioid use risk factors, and a more in-depth study is required to identify whether this could explain the observed differences in mortality in women of this age group.

The main cause of death was accidental poisoning, not intentional poisoning. Roxburgh et al.³⁸ have reported that the increase in opioid deaths was mainly caused by accidental overdoses in the Australian population, and some authors also found an increased risk of accidental death in the case of co-prescription³⁷. A previous study found that even the single prescription of opioids is associated with the risk of future ORD²⁹. Therefore, it is important to emphasize education and rationalize the use of these drugs to prevent accidents, as suggested by other authors^{37,38}, especially in men whose death rates are higher compared with women in Spain.

The comparison of the standardized rates of opioid-related mortality between Spain and the USA is significant. Even after standardization, the ratios are clearly different between the countries, 8–12 times higher in the USA compared with Spain, depending on the year (the more recent, the greater the difference), and this difference is more pronounced in men, in accordance with the results by Gomes et al.¹⁹ In this regard, Bosetti et al. have reported that the Southern and Eastern European countries (Spain included) have the lowest consumption², which would imply, *a priori*, a lower risk. Additionally, a recent study of Chen et al. shows that, in Europe, the most concerning increases in drug overdose deaths from opioids have been observed in the northern countries such as Estonia, largely caused by fentanyl³⁹.

The previous considerations indicate that, despite the increase in mortality, the situation in Spain is far different from the situation in the United States or some other countries^{2–4}.

Finally, we have to point out some limitations of this study. The use of secondary data is always a potential limitation, although the data were collected exactly as we needed for the purpose of the study, with precise definitions using ICD-10 codes. In addition, the data were obtained from reliable sources. However, the reliability of the determination and coding of the cause of death depends on each professional in each of the deaths, and not on the data source itself. Because of this, we believe that there is a possibility of underestimating the number of ORD, as in some cases this information may be omitted to avoid legal or administrative issues, especially in the case of accidents. Among the strengths of our study, we highlight the comparison between countries, as it provides information whether the situation in Spain is similar to the situation in the USA. Finally, the importance of the subject addressed here is another strength of the study.

Conclusion

The crude rate of ORD per 10⁵ inhabitants has changed from 1.68 in 2008 to 2.25 in 2017 in Spain, with around 30,000 years of life lost per year, being middle-aged men and women over 65 the most affected groups. The standardized rates in US population are 8–12 times higher compared to standardized rates in Spain. An opioid overuse crisis does not seem a likely scenario in Spain. However, it is a social problem that requires special health surveillance, particularly in middle-aged men and women over 65.

Opioids in the Treatment of Pain. Beliefs, Knowledge, and Attitudes of the General Spanish Population. Identification of Subgroups Through Cluster Analysis

Helena de Sola, MSc, Alejandro Salazar, PhD, María Dueñas, PhD, and Inmaculada Failde, PhD
Preventive Medicine and Public Health Area (H.d.S., I.F.), University of Cádiz, Cádiz; The Observatory of Pain (External Chair of Pain) (H.d.S., A.S., M.D., I.F.), University of Cádiz, Cádiz; Grünenthal Foundation-University of Cádiz, Cádiz; Institute of Research and Innovation in Biomedical Sciences of the Province of Cádiz (INIBICA) (H.d.S., A.S., M.D., I.F.), Cádiz; and Department of Statistics and Operational Research (A.S., M.D.), University of Cádiz, Cádiz, Spain

Abstract

Context. A lack of information has been found related to patients' perception toward pain management.

Objectives. To analyze the point of view of the general Spanish population regarding the use of opioids in pain treatment. To identify groups of individuals based on this information.

Methods. Nationwide cross-sectional study on a representative sample of 1299 Spanish adults. Data were collected on beliefs, knowledge, fears, opinions, and attitudes toward the use of opioids. A cluster analysis to identify groups of people based on these parameters and a multinomial logistic regression model to analyze the variables related to the clusters were performed.

Results. Three groups of subjects were identified based on their perspective toward opioids: a first group with a positive point of view ($N = 448$) composed of people older than 65 years who would accept a treatment if prescribed and who were less fearful of these drugs; a second group with a moderate point of view ($N = 337$) formed by younger subjects with university education, better informed about opioids, afraid of these drugs (odds ratio [OR] 2.67), and more frequently associated them with drowsiness (OR 2.58), nausea (OR 3.04), and tolerance (OR 2.16); and a third group with a negative point of view ($N = 468$), with lower educational level who would more often reject treatment with opioids, more afraid of them (OR 3.95), considering that they may not be able to stop the treatment (OR 3.04) and may produce tolerance (OR 3.03).

Conclusion. The different perspectives of patients regarding the use of opioids to treat pain should be taken into consideration by the physician when designing strategies to inform patients about the treatment of pain with opioids. This should promote their correct use, specially preventing their misuse. *J Pain Symptom Manage* 2018;55:1095–1104. © 2017 American Academy of Hospice and Palliative Medicine. Key Words

Opioids, beliefs, knowledge, attitudes, opiophobia, epidemiology

Introduction

Opioids are drugs that are widely used in pain treatment worldwide and that the World Health Organization considers essential for the control of moderate and intense pain, particularly of oncological origin.¹ For some years now, awareness has

been on the rise regarding the treatment of pain in Spain because of the progressive increase in the number of pain units in hospitals and of the enhanced emphasis on pain management in the palliative care. Likewise, the prescription and use of opioids increased between 2008 and 2015 in Spain² but

without reaching the levels observed in other European countries like Denmark.³

Several studies have shown that some patients consider that the medical prescription of opioids is sometimes associated with terminal illness and imminent death.⁴ Likewise, these drugs have also been related to negative side effects, such as excessive sedation, respiratory failure, urinary retention, or constipation, among others.⁵ This situation along with social, cultural, and historical factors⁶ has led to what is known as opiophobia, a set of inappropriate attitudes and beliefs regarding the deleterious effects of opioid administration for pain relief.⁷ This has been related to reduced prescription of these drugs by health professionals and lower consumption by patients.⁸

By contrast, in other countries where the prescription of opioids has risen considerably in recent years, it has been reported that between 24.0% and 37.1% of the patients with chronic pain may often misuse these drugs (defined as the use of any addictive drug in a manner other than how it is indicated or prescribed),⁹ which has raised some alarm among this population.¹⁰ This situation has led to the need to identify patients at risk and to monitor their behavior more closely.¹¹

In view of the differences observed in studies into the viewpoints of patients regarding the use of opioids to treat pain, we conducted a population-based survey to determine the current beliefs, opinions, and attitudes of the Spanish population toward opioid use in the treatment of pain. We set out to identify groups of individuals based on their point of view regarding these drugs and to analyze the factors that influence this perspective in each of the identified groups.

Methods

This cross-sectional study was carried out on a representative sample of the general adult population in Spain, obtained using a multistage stratified sampling method. The eligible population consisted of individuals aged 18 years and older who resided in households with a landline telephone, who agreed to participate in the study, and who were able to complete the questionnaire. The exclusion criteria were individuals younger than 18 years, lack of a landline telephone at home, or the inability to respond to the questionnaire.

Sampling Method

The Spanish territory was divided into eight strata or areas based on geographical and historical boundaries. For each stratum, 20 municipalities were randomly selected, taking into account the Spanish rural/urban ratio of 25:75 and considering municipalities with less than 10,000 inhabitants as rural and those with more than 10,000 inhabitants as urban areas.

The total number of subjects required for the study (see the following) was distributed in proportion to the size of each municipality. In addition, the number of subjects was divided into six strata, according to the sex and age distribution of the population (18–44, 45–64, and 65 or older). The selected individuals were contacted through their landline telephone using the Infobel España Office version 7.1 digital telephone directory (Kapitol SA/NV, Brussels, Belgium). This directory includes the telephone numbers of 90% of all Spanish households with a landline telephone, and considering that 80.6% of Spanish households have a landline telephone, we had access to 72.5% of the eligible Spanish population.

Sample Size

The sample size was determined based on the study of Schiller et al.,⁴ in which it was estimated that 50% of subjects were afraid of taking morphine. Setting a significance level of 95% and a precision level of 5%, the required sample size was established as 1155 subjects. To guarantee the number of subjects calculated and considering the response rate in a previous study involving a telephone survey,¹² the amount of telephone numbers randomly selected was three times that of the required sample size.

Procedure and Instruments

Data were collected via a computer-assisted telephone interview using the Skype and the SurveyMonkey platforms, whereby the interviewers recorded the data while the interview was being conducted. The interviewers received training on the purpose of the study, the working protocol, and on the use of the SurveyMonkey platform. In addition, data collection was coordinated and supervised on a daily basis by a member of the research team, addressing any problems that had arisen. Before the interview, all subjects included in the study gave their informed consent, and the study was conducted in accordance with the Declaration of Helsinki, using standard working procedures and protocols.

Survey Structure and Topic

The survey was structured in six blocks of questions: the first block was designed to obtain personal information; the second block was related to the respondents' beliefs about opioids, and in this case the information was collected from an open-ended question in which the interviewees were asked what was the first thing that came to mind when they heard the word opioid; the third block revealed the level of the respondent's contact with opioids and their knowledge of them; the fourth block explored the fears (side effects, death, becoming an addict, not

achieving the desired results, and death) related to the intake of opioids; the fifth block collected the opinions of the responder regarding this type of treatment (tolerance, dependence, and severity of the disease); and the sixth block addressed the responders' attitude toward these drugs. This attitude was obtained by means of a question that asked whether the respondent would agree to treatment with this medication or not if their doctor prescribed it. The questions that set out to collect information about beliefs, fears, and opinions were assessed using a five-point Likert scale (not at all, a little, some, quite a lot, and a lot).

To facilitate the analysis and interpretation of the results, three new variables were created. The first variable was designated as the level of contact with the treatment, and it was constructed using three questions that referred to the drugs tramadol, morphine, tapentadol, oxycodone, fentanyl, and buprenorphine. The questions were as follows:

1. "Are you currently following a treatment with any of these opioids?" If the answer was affirmative, we considered the respondent to have maximal contact with opioids.
2. "Have you ever been treated with any of these opioids?" If the answer was affirmative, we considered the respondent to have medium contact with opioids.
3. "Do you know anyone who is currently or has ever been treated with an opioid?" If the answer was affirmative, we considered the respondent to have minimal contact, whereas they were considered as having no contact if the response was negative.

A second variable, level of opiophobia, was established based on four questions gathering information about the individual's fear of side effects, becoming an addict, not achieving the desired results, and death. The responses to these questions were categorized on a scale ranging from 0 = not at all to 4 = a lot. The final score of this new variable was the sum of the scores given on a scale from 0 to 16, where 0 is equivalent to no opiophobia and 16 corresponded to maximal opiophobia.

In addition, to determine the respondents' knowledge about the opioids indicated previously, a third variable was created that we called correct identification of opioids based on the responses to the questions: "Have you heard of any of the following medications?"; and "Could you tell me which of the following drugs you think is an opioid?" The answers to these questions were dichotomous (yes and no), and we considered that an individual correctly identified the drugs only if they responded affirmatively to both questions.

Statistical Analysis

A descriptive analysis of the variables studied was carried out, calculating the frequency, central tendency, and dispersion. In addition, a hierarchical cluster analysis was performed to establish groups of individuals or patterns according to the subjects' opinions, fears, knowledge, level of contact, and attitudes toward opioids. The Euclidean distance between the groups and cluster formation criteria were used. Subsequently, the differences between the groups were analyzed using Chi-squared tests. In addition, a multinomial logistic regression model was established to determine the factors associated with each of the groups previously identified in the cluster analysis. The covariates included in this model were the significant variables identified in the bivariate analysis.

Results

General Characteristics of Respondents

We carried out 3844 contacts, 1299 of which were considered valid. The response rate was 33.79%. Of the total number of subjects interviewed, 50.7% were women, and the global average age of the cohort was 50.48 years (SD 15.9). Most subjects had completed secondary education (45.9%).

Morphine was the best-known medication (99.2%), and it was correctly identified by 64.9% of respondents. However, fewer subjects correctly identified tramadol (14.2%), and oxycodone was recognized by 11.3% of respondents, whereas fentanyl, buprenorphine, or tapentadol was only identified correctly by slightly more than 5% of them. More than 50% of participants knew someone who had taken opioid medication (minimal contact with treatment), although only 3.8% were taking any of these drugs at the time of the interview (maximum contact) (Table 1). Most subjects with maximum contact were women (60%), older than 65 years, and mainly with primary education (43%).

Beliefs, Fears, Opinions, and Attitudes Toward Opioids

Figure 1 shows a word cloud with the beliefs of the respondents with regard to opioids, where the size of each word indicates how often the respondents related it to opioids. Although the most frequent response was *I do not know with which word to relate them*, the words pain, illegal drugs, medications, opium, and painkillers were much repeated (Fig. 1).

With regard to fear of opioids (Fig. 2), side effects (48%) or of a failure to achieve the expected results (47%) were the fears most frequently reported by respondents, although nearly 35% of them expressed the fear of becoming addicted.

With regard to the respondents' opinions on opioids, most of the interviewed agreed that these drugs

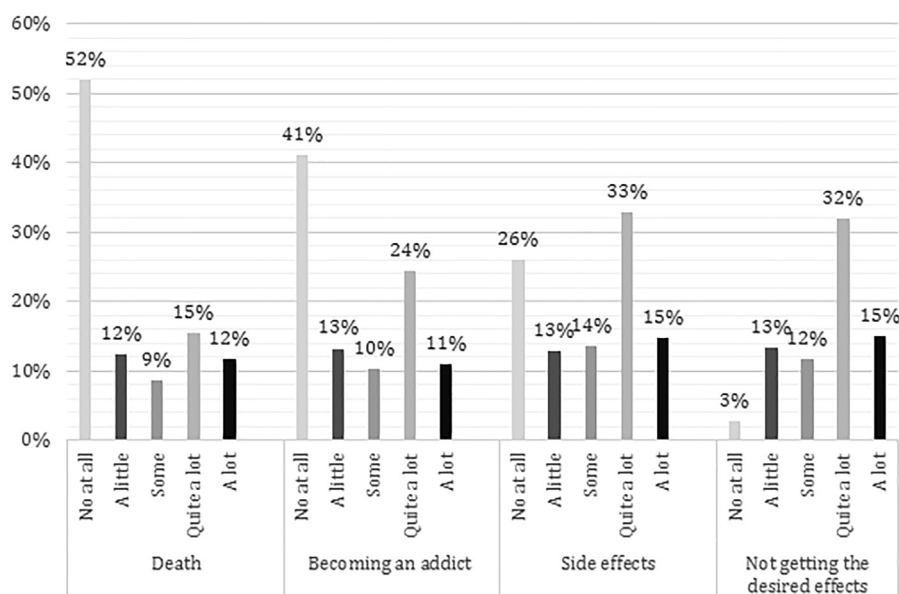

Fig. 2. Summary of respondents' fears associated with opioid usage.

associated with terminal illness, addiction, and tolerance.

Factors Associated to Each Group Identified According to Their Point of View Toward Opioids

The opinion that increasingly large doses of opioids are required (MPV: OR 2.16; NPV: OR 3.03) and a higher level of opiophobia (MPV: OR 2.67; NPV: OR 3.95) were the two variables most strongly associated with the groups with a worse vision of these drugs (MPV, NPV vs. PPV).

However, although respondents in the MPV group more strongly agreed that opioids produce sleepiness (OR 2.58) and nausea (OR 3.04), respondents with a more negative vision (NPV) placed more importance on not being able to stop taking them whenever they wanted to (OR 3.04) (Table 4).

Discussion

To our knowledge, this is the first study carried out in Spain to analyze the perspective of the general population toward opioids, based on the beliefs, knowledge, fears, and opinions. This analysis enabled us to identify three groups of individuals with a clearly distinct point of view regarding these drugs and specific factors associated with each of these groups.

Among the results obtained, it is noteworthy that most respondents did not have a clear idea about opioids and those who did mostly considered them to be related with pain, illegal drugs, and medication. This is consistent with the findings of a study carried out in Portugal,¹³ where 32.3% of the general population

were unable to recognize the term morphine. However, when these individuals were specifically asked about this drug, 99.2% answered that they knew about it although it was only identified as an opioid by 64.9% of them.

In our study, 3.8% of the respondents were under a treatment with opioids at the time of the survey. This is similar to the situation described in Portugal (4.37%)¹⁴ and Scotland, where the opioid use increased to 3.6%, mainly because of the use of tramadol.¹⁵ According to the report of the Spanish Agency of Medicines and Sanitary Products,² tramadol is the opiate that has experienced a greater increase in use in recent years, which may explain why it is the best-known opioid after morphine in our study.

It is important to note that three different profiles of participants were identified in this study, including a group of better-informed young people who are more concerned about the side effects of opioids, who have a more critical attitude toward opioids, and who are less willing to take them on medical prescription (MPV). Another group of participants with a generally lower educational level (NPV) seemed to show more deep-rooted opiophobia. Finally, there was a group of older respondents who had more confidence in their physician when these drugs were prescribed, and they were less concerned about their adverse effects (PPV). In this vein, it is noticeable that, as other studies show, elderly patients assume pain and taking medication as part of their aging process, and only 15% expect that the treatment has few side effects.¹⁶ This could explain the results found in our study regarding older people being less afraid of the adverse effects associated with opioids.

Table 2
Respondents' Opinion Associated With Opioid Use

Respondents' Opinion on Opioids		
Variables	Categories	%
Respondents' opinion on opioids tolerance		
Increasingly larger doses are required	Completely disagree	14.3
	Slightly disagree	16.3
	Moderately agree	44.7
	Strongly agree	18.2
	Undecided	6.5
Respondents' opinion on opioids' dependence		
There is a risk of being unable to stop taking them	Completely disagree	22.7
	Slightly disagree	23.6
	Moderately agree	34.7
	Strongly agree	10.1
	Undecided	8.9
Respondents' opinion on opioids' side effects		
They may cause somnolence	Completely disagree	4.5
	Slightly disagree	8.5
	Moderately agree	50.8
	Strongly agree	22.1
	Undecided	14.2
They may cause constipation	Completely disagree	7.2
	Slightly disagree	11.7
	Moderately agree	24.8
	Strongly agree	8.7
	Undecided	47.6
They may cause nausea	Completely disagree	6.5
	Slightly disagree	11.2
	Moderately agree	42.2
	Strongly agree	13.5
	Undecided	26.6
They may cause nervousness	Completely disagree	20.4
	Slightly disagree	15.5
	Moderately agree	31.1
	Strongly agree	9.2
	Undecided	23.8
Respondents' opinion on severity of the disease		
Opioids are only for terminally ill patients	Completely disagree	49.7
	Slightly disagree	15.5
	Moderately agree	22.1
	Strongly agree	8.2
	Undecided	4.5
Opioids use means that the illness is serious	Completely disagree	24.6
	Slightly disagree	13.1
	Moderately agree	42.6
	Strongly agree	15.7
	Undecided	4.0
Opioids should be the last treatment option	Completely disagree	22.3
	Slightly disagree	12.9
	Moderately agree	37.4
	Strongly agree	18.1
	Undecided	9.3

Similarly, the higher educational level of the youngest group in our study could condition their attitudes, making them more demanding with the treatment. The World Health Organization states that, among other educational organizations, universities play a key role in establishing knowledge, behavior, and attitudes toward health, promoting the empowerment of students in health, and enabling them to better control adverse health determinants.¹⁷ This could explain why the youngest group with the highest proportion of individuals with university education is indeed more critical, not only of the most

well-known aspects of these drugs like addiction and tolerance but also of other less common aspects that may affect their quality of life.

Studies have shown that when taking opioids, confidence in their effects and a positive attitude toward them is closely related to the improvement in the quality of life and the pain relief obtained by the patient or that described by acquaintances and relatives.^{18,19} This circumstance could explain the results observed in the PPV group, which was precisely the group with the greatest level of contact with these drugs. An alternative explanation could be that a greater exposure to opioids expels the fear of their adverse effects, tipping the balance in favor of their pain-relieving effects. This hypothesis could be particularly relevant if we consider that this group included an older population that might be more concerned about pain relief and less concerned about the side effects of these drugs.^{18,19}

Tolerance was identified as a risk in both the MPV and NPV groups. The NPV group referred to the risk of being unable to stop taking opioids; these individuals were more reluctant to accept them if prescribed by a doctor. One of the reasons for maintaining inappropriate beliefs and attitudes toward these drugs may be a lack of knowledge about them, leading to opiophobia, a phenomenon that includes a fear of tolerance.⁷ This is consistent with the characteristics of the NPV group, where the respondents attained a generally poorer level of education.

In accordance with our results, fear of addiction has previously been shown to be an important barrier to opioid use in patients suffering moderate or severe chronic pain, representing one of the reasons why this pain is often undertreated.^{20,21} Indeed, opioid use in the U.S. represents 80% of the total worldwide consumption,^{22,23} and the misuse behavior rate is 34.1%,²⁴ much higher than in other countries. Given the importance of controlling pain in patients with chronic moderate or severe pain and avoiding problems of the misuse of opioids, it is important to find a balance between these two extremes in the Spanish population. Thus, identifying groups with different perceptions toward opioids, such as those observed in the present study, should be useful when establishing future health care strategies.

Finally, some strengths and weaknesses of the present study should be noted. One strength that stands out in this work is the cluster analysis used to identify different groups of subjects based on beliefs, fears, opinions, and attitudes toward opioids. Other studies^{12,25} have applied this analysis to cohorts of patients with chronic pain, demonstrating its usefulness. However, as far as we know, this is the first time that this type of analysis has been applied in this kind of study. Another strength is that the study was carried

out on a large sample from the general population using an exhaustive sampling procedure, representing populations of different ages and sex.

Among the weaknesses of the study, we must consider that the information was gathered by telephone, which limited the duration of the interview.

However, the use of telephone surveys has been considered by some to be more adequate in population studies than face-to-face surveys,²⁶ particularly because they allow greater coverage of the population being studied and they permit a representative sample to be obtained by randomization of telephone

MPV = moderate point of view, group with a moderate vision of opioids; NPV = negative point of view, group with a negative vision of opioids; OR = odds ratio. Goodness of fit to the model: $\chi^2 = 1482.7$; df = 20; $P < 0.001$.

Reference group of the dependent variable: Group with a positive vision of opioids (positive point of view).

^aReference category.

numbers. Another issue that must be taken into account is the low response rate observed in this study (33.79%), which could have introduced selection bias. However, we consider that this is unlikely to affect the validity of the results because the distribution of the sample is identical to that of the target population, ensuring that the responses are representative. Furthermore, although higher response rates have been obtained (e.g., 70%),²¹ rates similar to ours (33% and 42%) were also reported using the same method.^{27,28}

Another possible limitation is that we did not assess opiophobia directly, and its measurement was based on four questions about the individual's fear (side effects, becoming addicted, not achieving the desired results, and death). However, the term opiophobia, as previously described in the introduction section,⁷ is a definition that includes similar issues as those considered in this article. Given that the general population was target in this study, we believe that the inclusion of the exact definitions of both tolerance and dependence in the questionnaire would have complicated the collection data.

In summary, demonstrating the lack of knowledge in the Spanish population about opioids, this study shows that the side effects of these drugs are the most feared aspects associated with their use in the treatment of pain. Furthermore, this study reveals the factors related with the different perceptions and concerns among the general population regarding the use of opioid treatments, which largely depends on educational level, age, and prior contact with opioids. Health care professionals should pay particular attention to the patient profile when designing strategies to inform patients and treat their pain using opioids. The information given should be personalized to suit the patient's characteristics, paying special attention to the possible benefits of the treatment in the MPV and NPV groups and to the risks and adverse effects in the group with PPV. This should improve the clinical management of opioids and promote their correct use, specially preventing their misuse.

Disclosures and Acknowledgments

This work was supported by the External Chair of Pain, a collaboration between the University of Cádiz and the Grünenthal Foundation. The Grünenthal Foundation is a private nonprofit making organization that promotes the dissemination of scientific knowledge and supports research. The authors acknowledge the effort of the interviewers who collected the data through the telephone interviews.

Dear Ms De Sola,

Thank you very much for the revised version of your manuscript "Living with opioids: A qualitative study with patients with chronic low back pain." (HEX-2019-3385.R2). I am pleased to accept it for publication in Health Expectations.

The final version of your article cannot be published until the publisher has received the appropriate signed license agreement. Once your article has been received by Wiley for production the corresponding author will receive an email from Wiley's Author Services system which will ask them to log in and will present them with the appropriate license for completion.

Payment of your Open Access Article Publication Charge (APC):

All articles published in Health Expectations are fully open access: immediately and freely available to read, download and share. Health Expectations charges an article publication charge (APC).

Before we can publish your article, your payment must be completed. The corresponding author for this manuscript will have already received a quote email shortly after original submission with the estimated Article Publication Charge; please let us know if this has not been received. Once your accepted paper is in production, the corresponding author will receive an e-mail inviting them to register with or log in to Wiley Author Services (www.wileyauthors.com) where the publication fee can be paid by credit card, or an invoice or proforma can be requested. The option to pay via credit card and claim reimbursement from your institution may help to avoid delays with payment processing

You will be hearing in due course from a member of the Production Team who will send page proofs and any production queries.

Thank you again for your contribution.

Yours sincerely,

Professor Carolyn Chew-Graham
Editor, Health Expectations
